Right ventricular (RV) dysfunction has been associated with worse prognosis in patients with heart failure and left ventricular (LV) systolic dysfunction.1–5 Cardiac resynchronization therapy reduces the risk of death and heart failure events in patients with heart failure, low ejection fraction, and a wide QRS,6–11 in conjunction with improvement in both LV size and function, as well as RV size and function.12–16 In patients with severe heart failure and those with severe RV dysfunction may respond poorly to cardiac resynchronization therapy (CRT).17,18 The effect of CRT on RV function (RVF) and the relationship between RVF and outcomes in patients with mild heart failure are less clear.

Background—Right ventricular function (RVF) is an important determinant of outcome in patients with heart failure, and those with severe RV dysfunction have worse outcome after cardiac resynchronization therapy (CRT). We used data from the Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy (MADIT-CRT) Trial to determine whether therapy with CRT is influenced by or affects RV function and to define the relationship between RV function and outcomes.

Methods and Results—A total of 1820 patients were randomly assigned to CRT plus implantable cardioverter defibrillator or implantable cardioverter defibrillator-only in a 3:2 ratio. We assessed RVF as RV fractional area change by echocardiography at baseline and after 1 year of therapy (n=1511 and 1273, respectively). The median RV fractional area change was 41%, with 10.9% of patients <35% at baseline. Baseline RVF did not modify the treatment effect of CRT on the primary outcome (interaction \( P = 0.19 \)). Randomization to CRT-implantable cardioverter defibrillator was associated with a greater improvement in RVF (ARV fractional area change 8.1% versus 5.4%; \( P < 0.001 \)), and improvement in RVF was related to subsequent outcomes. Every 5-point increase in RV fractional area change was associated with a 22% reduction in event rates (hazard ratio, 0.78; 95% confidence interval, 0.66–0.92; \( P = 0.003 \)), although this was not independent of the concurrent improvement in left ventricular function. Baseline tricuspid regurgitant velocity, a measure of pulmonary systolic pressure, was predictive of events in a multivariate analysis (hazard ratio, 1.86; 95% confidence interval, 1.24–2.8; \( P = 0.003 \)).

Conclusions—In this population with mild heart failure symptoms, CRT was associated with improvement in RVF, which improved in parallel with improvement in left ventricular function. Patients with the best RVF at 1 year demonstrated the lowest subsequent event rates.

Key Words: cardiac resynchronization therapy ■ heart failure ■ right ventricle

Right ventricular (RV) dysfunction has been associated with worse prognosis in patients with heart failure and left ventricular (LV) systolic dysfunction.1–5 Cardiac resynchronization therapy reduces the risk of death and heart failure events in patients with heart failure, low ejection fraction, and a wide QRS.6–11 in conjunction with improvement in both LV size and function, as well as RV size and function.12–16 In patients with severe heart failure and those with severe RV dysfunction may respond poorly to cardiac resynchronization therapy (CRT).17,18 The effect of CRT on RV function (RVF)

Clinical Perspective on p 442

The Multicenter Automatic Defibrillator Implantation Trial-Cardiac Resynchronization Therapy (MADIT-CRT) Trial was designed to test the hypothesis that CRT would reduce death and heart failure events in patients with New York Heart Association (NYHA) class I and II symptoms of heart failure, low ejection fraction, and a wide QRS complex.
MADIT-CRT showed a 34% reduction in the primary end point of death or heart failure events in patients randomized to the CRT plus implantable cardioverter defibrillator (ICD) group (CRT-D group). We used echocardiographic data at baseline and after 1-year follow-up from MADIT-CRT to determine the prevalence of RV dysfunction in patients with NYHA class I and II heart failure being considered for CRT, to assess the effect of CRT on RVF, and to determine whether RVF modified the treatment effect of CRT.

Methods

Study Population
The MADIT-CRT Trial enrolled 1820 patients from 110 centers in the United States, Canada, and Europe from December 2004 to April 2008. Included patients were >21 years of age with mildly symptomatic heart failure (NYHA class I and II if ischemic cardiomyopathy, and NYHA class II if nonischemic cardiomyopathy), low ejection fraction (≤30%), as determined by the enrolling site, with a QRS duration of ≥130 ms. The details on inclusion and exclusion criteria and the primary results from the study have been published previously. Individual institutional review boards approved the protocol, and each patient provided written informed consent that included consent for echocardiographic analyses.

Patients were randomly assigned to CRT-D therapy versus ICD-only therapy in a 3:2 ratio. In the ICD-only group, the pacing mode was programmed as VVI for single chamber units and DDI for dual chamber units, both with lower rates set to 40 beats per minute and hysteresis turned off. Echocardiograms were obtained at baseline before device implantation (n=1809) and at follow-up 12 months later (n=626 ICD group; n=752 CRT-D group). Assessment of RVF by RV fractional area change (RVFAC) was possible in 1511 patients at baseline (n=610 ICD group; n=901 CRT group) and 1273 at 1-year follow-up (n=544 ICD group; n=729 CRT group), with paired data available in 1126 patients. Tricuspid regurgitant (TR) velocity was possible in 609 patients at baseline and 576 patients at 1-year follow-up. It should be noted that B-type natriuretic peptide data were available in only 1197 patients, all of whom were from US sites.

Echocardiographic Measures
Echocardiograms were sent on digital media storage or on videotape to Brigham and Women’s Hospital, where LV, RV, and left atrial (LA) measurements were made by a single technician at the echocardiographic core laboratory according to established American Society of Echocardiography protocols. LV volumes were measured by Simpson’s method of discs in the apical 4-chamber and 2-chamber views, and averaged. LV ejection fractions (LVEF) were calculated accordingly. LA volumes were measured by Simpson’s method of discs in the apical 4-chamber view. RVFAC was calculated as the difference in RV diastolic and systolic areas, divided by the diastolic area, in the apical 4-chamber view. TR velocities were measured according to standard protocols. Maximum peak TR velocity was measured from the view where continuous wave Doppler velocity reading was highest. Patients with undetectable, inadequate, or difficult to visualize envelopes of TR were excluded from the analysis. Approximately 70% of MADIT-CRT studies were digital. For videotape studies, these were initially digitized to digital loops, and all studies were subsequently analyzed in the same manner. To estimate the amount of pacing of the RV in the ICD-only group, device interrogation analysis was performed on a random sample of 90 ICD-only patients.

Statistical Analyses
Differences in baseline characteristics between those patients in whom RVFAC could be measured and those patients in whom it could not be measured were assessed with χ² test for categorical variables and t tests or ranksum for continuous variables. Similarly, comparisons were made between subgroups above and below 2 cutoffs of RVF (RVFAC <35% and ≥35%, and median of 41% and >41%). The treatment effect was compared in the subgroups based on the 2 cutoffs for RVF described above, and the interaction between subgroup and treatment effect with respect to outcomes was assessed.

The primary outcome of the trial was a composite outcome of death attributable to any cause or a nonfatal heart failure event, as adjudicated by an independent end points committee unaware of treatment assignment. The relationship between baseline RVF and outcomes was assessed using an unadjusted Cox proportional hazards model. The primary event rate was calculated in each quartile of baseline RVF in each treatment group. The relationship between RVF at 1 year and change in RVF from baseline to 1 year, and the outcomes subsequent to the 1-year echocardiogram were assessed in a landmark type analysis using the Cox proportional hazards model, adjusted for treatment status and further adjusted for change in LVEF and treatment group. The primary event rate subsequent to 1 year was calculated in each quartile of 1-year RVF in each treatment group.

Results
Assessment of RVF was possible in 1511 at baseline and 1273 at 1 year. RVFAC was normally distributed in the MADIT-CRT population at baseline (Figure 1). We divided the population into those with RVFAC above and below 35% based on the American Society of Echocardiography definition for RV dysfunction, and by this definition, 164 patients or 10.9%...
of the population had evidence of RV dysfunction. Because the majority of patients had an RVF within the normal range, we also divided the population above and below the median RVFAC of 41%.

The 298 patients who did not have RVF assessed at baseline differed minimally from those who had RVF assessed, although they were more likely to have had a history of ventricular arrhythmia (10.9% versus 6.5%; \( P = 0.007 \) ) and had higher diastolic blood pressure at baseline (72.8±10.5 versus 71.3±10.3; \( P = 0.021 \)).

Assessment of TR velocities was possible in 609 patients at baseline (40.3%) and 576 (45.2%) at 1 year.

**Baseline Echocardiographic Characteristics**

Patients with a lower RVF by either criterion had larger LV volumes, larger LV dimensions, higher LA volumes, and lower LVEF (Table 2). Random interrogation of devices in patients treated with ICD-only revealed that for patients with single chamber units, 83% had no RV pacing, 15% had ≤5% RV pacing, and only 2% had >5% RV pacing. Of those with dual chamber units, 87% had no RV pacing, 7% had ≤5% RV pacing, and 6% had >5% RV pacing.

**RVF at Baseline and Outcomes**

We observed no clear relationship between baseline RVF and outcomes in either treatment group (ICD group: hazard ratio [HR], 1.02; 95% confidence interval [CI], 0.98–1.04; \( P = 0.736 \)  and CRT group: HR, 0.98; 95% CI, 0.95–1.02; \( P = 0.313 \) ), although the primary event rates were substantially lower in the patients receiving CRT compared with those treated with ICD-only (Figure 2). To examine whether RVF modified the treatment effect of CRT, we assessed for interaction between baseline RVF and treatment effect on outcome and observed no evidence of a baseline RVF-treatment interaction (RVFAC above and below 35%; interaction \( P = 0.346 \); RVFAC above and below median; interaction \( P = 0.194 \)).

ACEI indicates angiotensin-converting enzyme inhibitor; β-Blocker, β-adrenergic receptor blocker; BMI, body mass index; BNP, B-type natriuretic peptide; CRT-D, cardiac resynchronization therapy with defibrillator; eGFR, estimated glomerular filtration rate; HTN, hypertension; ICD, implantable cardiac defibrillator; IVCDD, interventricular conduction delay; LBBB, left bundle-branch block; MI, myocardial infarction; NYHA, New York Heart Association class; RBBB, right bundle-branch block; RVFAC, right ventricular fractional area change.
Change in RVF from Baseline

The majority of patients had a repeat echo at 1 year, and RVF assessment was possible in 1273 patients. RVF improved to a greater extent in the CRT group than in the ICD group with an absolute change from baseline in RVFAC of 8.1±5.5% versus 5.4±4.8% (P<0.001). This improvement occurred in parallel with changes in LVEF (Figure 3); for each increasing quartile of improvement in LVEF, RVFAC improvement similarly increased. The improvement also occurred in parallel with changes in LV end-diastolic volume index, LV end-systolic volume index, and LA volume as previously reported (Table 3).

RVF at 1 Year and Outcomes

We assessed the relationship between RVF at 1 year and subsequent primary end points, in a landmark type analysis. RVF at 1 year was better in the CRT group than in the ICD group and was related to subsequent outcomes in the CRT but not in the ICD group (CRT group: HR, 0.92; 95% CI, 0.88–0.98; P=0.005; ICD group: HR, 0.98; 95% CI, 0.93–1.03; P=0.48; interaction P=0.078; Figure 4). Each 5% absolute increase in RVFAC from baseline was associated with a 28% reduction in risk of the primary outcome, after adjusting for baseline RVF (HR, 0.72; 95% CI, 0.59–0.87; P=0.001). This association remained after adjusting for change in LVEF during the same period, RVF was no longer an independent predictor of outcome (HR, 0.97; 95% CI, 0.76–1.25; P=0.828). We report adjustment for LVEF because it is a measure that is easily comprehended and obtained; however, change in RVF was similarly no longer an independent predictor after adjusting for change in LV end-diastolic volume, LV end-systolic volume, and LA volume during the same time period.

TR Velocity at Baseline and 1 Year

TR velocity, a measure of the gradient between the RV and the right atrium and an indirect measure of pulmonary pressures, was similar at baseline in those randomized to CRT-D or to ICD-only (Table 2). Baseline TR velocity was predictive of the primary end point, even after adjusting for treatment group, baseline LVEF, and baseline RVFAC (HR, 2.01; 95% CI, 1.35–2.99; P=0.001), and in a more fully adjusting model adjusting for treatment, age, sex, ischemic status, diabetes mellitus, status, estimated glomerular filtration rate, QRS width, NYHA class, baseline LVEF, and baseline RVFAC (HR, 1.86; 95% CI, 1.24–2.8; P=0.003); there was no interaction between baseline TR velocity and treatment effect on outcome (P=0.596). In 576 patients with repeat TR velocity measures, TR velocity decreased by −0.07±0.49 m/s in the CRT-D arm compared with an increase of 0.05±0.44 m/s in the ICD-only arm, (P=0.014). TR velocity at 1 year was predictive of subsequent events, irrespective of treatment arm (ICD group: HR, 1.93; 95% CI, 1.04–3.58; P=0.036; CRT group: HR, 3.48; 95% CI, 1.45–8.32; P=0.005). However, when adjusted for change in LVEF and RVF, it was no longer predictive of events.
Discussion

We observed a low prevalence of RV dysfunction, as defined by American Society of Echocardiography criteria as an RVFAC of <35%, in MADIT-CRT patients with mild heart failure being randomized to CRT-D or ICD-only therapy. In contrast to other studies, RVF at baseline was not related to outcomes in this population, perhaps related to the low prevalence of RV dysfunction in this cohort of NYHA class I and II heart failure patients. Although RVF itself did not modify the treatment effect of CRT, treatment with CRT was associated with improvement in RVF and a reduction in TR velocity, a measure of pulmonary pressures, which occurred in parallel with improvements in LV volumes and ejection fraction, as well as LA volumes. Patients with the best RVF at 1 year had a lower subsequent event rate, although this improvement was not independent of the observed improvement in LV function.

Reduction in pulmonary artery pressure with concomitant reverse remodeling of the RV has been demonstrated in some small studies of patients with NYHA class III and IV heart failure symptoms treated with CRT. Other small studies have failed to show any improvement in RVF with CRT, despite favorable changes to LV function. The Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction (REVERSE) Trial Investigators looked at the effect of CRT on longitudinal RV motion as measured by tricuspid annular plane systolic excursion and found that CRT was not associated with any clinically significant effect on tricuspid annular plane systolic excursion or pulmonary arterial pressures, despite significant improvement in LVEF. The lack of change in RVF as measured by tricuspid annular plane systolic excursion in the REVERSE Trial may reflect the inherent limitations of this measure. Assessment using this technique is restricted to longitudinal motion of the RV free wall and it assumes that the displacement of this segment represents the function of the complex 3-dimensional (3D) structure of the RV, but it disregards the contribution of the interventricular septum and the right ventricular outflow tract to overall RVF. Using a more global measure of function, RVFAC, we found significant improvement in RVF in patients treated with CRT in parallel with improvement in LV size and function, as well as pulmonary pressures (Table 3). This measure of RVF has been shown to be predictive of outcomes in patients with heart failure after myocardial infarction and in pulmonary embolism. In most patients who have not been subject to markedly elevated pulmonary pressures, RVF measured by RVFAC serves primarily as an assessment of the RV response to increased afterload, rather than a measure of intrinsic RV contractile function.

LA vol index, left atrial volume indexed to body surface area; LVEDS index, left ventricular end-systolic volume indexed to body surface area; LVEDV index, left ventricular end-diastolic volume indexed to body surface area; LVEF, left ventricular ejection fraction; RVEDA index, right ventricular end-diastolic area indexed to body surface area; RVFAC, right ventricular fractional area change; and TR velocity, maximum velocity of the tricuspid regurgitant jet.
method has been shown to correlate well with MRI-derived RVF; nevertheless, this diagnostic assessment using the fractional area change method may not accurately represent true RVF. The RV is a complex geometric 3D structure, and 2D echocardiographic assessment using the fractional area change method is statistically significant, although clinically relatively trivial. Because of the large sample size, some of the differences between patients with higher and lower FAC measures were not independent of the improvement in LVEF and RVF. Pulmonary arterial pressures have proven prognostic value in patients with heart failure, where pulmonary arterial systolic pressures of >45 mm Hg are generally associated with worse prognosis. Patients in the MADIT-CRT population, however, had TR velocities suggestive of much lower pulmonary pressures; nevertheless, TR velocity remained prognostically important. Lower TR velocity at 1 year was associated with improved outcomes, but was not independent of the improvement in LVEF and RVF, suggesting that these improvements may indeed occur in response to profound improvements in LV function and size that occur as a result of CRT.

A number of limitations of our analysis should be noted. Because of the large sample size, some of the differences between patients with higher and lower FAC measures were statistically significant, although clinically relatively trivial. The RV is a complex geometric 3D structure, and 2D echocardiographic assessment using the fractional area change method may not accurately represent true RVF; nevertheless, this method has been shown to correlate well with MRI-derived RVEF and has been one of the more robust methods to assess RVF. We did not use other methods to assess RVF in this analysis. As RVF assessment was available in only 83% of patients at baseline and 70% at 1 year, we cannot assess the relationship between RVF and outcome in those who did not have these measures. Although Doppler transthoracic echocardiographic assessment of TR jet peak velocity has been shown to predict pulmonary arterial systolic pressure accurately as observed by invasive measures, it is a technique with inherent potential limitations. Measurement of peak TR jet velocity requires an adequate TR envelope, which is frequently not possible or inadequate, especially in patients without clinically significant TR. This limitation led to exclusion of TR velocity data from a large number of patients in this study. Finally, overall RVF in the MADIT-CRT cohort was generally preserved, and the relationship between RVF and outcome in a population with more severely symptomatic heart failure will likely differ from what we observed in MADIT-CRT.

In summary, in patients in the MADIT-CRT cohort with mild symptoms of heart failure baseline RVF was not predictive of outcomes and did not modify the response to CRT treatment. However, patients treated with CRT had greater improvement in RVF and greater reduction in TR velocities than those in the ICD-only arm, regardless of baseline RVF. These changes occurred in parallel with improvement in LV structure and function and LA size. Improvements in RVF and TR velocities were predictive of better subsequent outcomes; however, this was not independent of the improvement in LV function, suggesting that improvement in RVF and TR velocities is likely secondary to improvement in LV function in this population.

Sources of Funding
The MADIT-CRT Trial was funded by Boston Scientific, through a research grant to the University of Rochester, which, in turn, provided funding for core laboratories, including the echocardiography core laboratory.

Disclosures
Drs Solomon, Foster, and Moss received research support for the conduct of the MADIT-CRT Trial from Boston Scientific through a grant given to the University of Rochester. Drs Solomon and Pfeffer served as consultants to Boston Scientific. The other authors have no conflicts to report.

**CLINICAL PERSPECTIVE**

Right ventricular function (RVF) is a known predictor of adverse outcome in patients with heart failure. We assessed RVF at baseline and follow-up in patients being randomized to cardiac resynchronization therapy or implantable cardioverter defibrillator only in the Multicenter Automatic Defibrillator Implantation Trial-Cardiac Resynchronization Therapy Trial. Although baseline RVF was well preserved in this relatively low-risk New York Heart Association class I and II population and was not itself a predictor of outcome, RVF did improve with cardiac resynchronization therapy and those patients with the best right ventricular function at 1 year had the best subsequent outcomes. These data suggest that right ventricular function may be a marker for cardiac resynchronization therapy response, and improvement in RVF may identify a group of patients who will have lowest subsequent event rates after cardiac resynchronization therapy.
Right Ventricular Function, Pulmonary Pressure Estimation, and Clinical Outcomes in Cardiac Resynchronization Therapy
