Development of Therapeutics for Heart Failure

Contemporary Drug Development in Heart Failure
Call for Hemodynamically Neutral Therapies

Muthiah Vaduganathan, MD, MPH; Javed Butler, MD, MPH; Bertram Pitt, MD; Mihai Gheorghiade, MD

Until now, successful drug development in chronic heart failure (HF) with reduced ejection (HFrEF) has followed a conceptual model of targeting the secondary consequences of HF and its associated peripheral maladaptive processes leading to cardiovascular adverse remodeling. Step-wise modulation of angiotensin-II, the adrenergic system, and aldosterone have contributed to reductions in mortality in chronic HFrEF. Moreover, other vasodilators, such as hydralazine and nitrates, have improved outcomes in African American patients with HFrEF. Similarly, the combination of a neprilysin inhibitor and an angiotensin-II receptor blocker (ARB) provided incremental improvement in cardiovascular outcomes albeit at the cost of a higher risk of hypotension. The introduction of many other novel HFrEF agents beyond these therapies has largely failed, and the outcomes for these patients, especially after hospital discharge, have remained relatively stagnant and exceedingly high.1

To date, almost all disease-modifying therapies in HFrEF cause blood pressure lowering as an intended or unintended consequence. Low systolic blood pressure (SBP), which may reflect the extent of myocardial reserve, is one of the strongest determinants of clinical course in ambulatory and hospitalized patients with HFrEF.2 Hypotension, especially in high-risk or susceptible patients, presents a major hurdle to the contemporary HFrEF drug development paradigm and will likely pose an even greater obstacle once sacubitril/valsartan achieves widespread clinical application. The continued addition of hemodynamically active novel agents does not seem to be a practical or sustainable approach to further optimize HFrEF outcomes. Herein, we critically explore recent trends in the HFrEF drug development pipeline and discuss the importance of shifting to a strategy of developing therapies that directly target primary cardiac abnormalities without significantly influencing blood pressure or heart rates.

Risks of Hypotension
Optimal blood pressure is critical for maintaining adequate coronary and renal perfusion pressures, especially in patients with overt or subclinical vascular disease. Patients with elevated left ventricular end diastolic pressures with hemodynamic congestion,3 those with pre-existing coronary artery disease,4 and collateral dependent areas of myocardial perfusion are at particular risk of jeopardizing coronary perfusion pressure with systemic hypotension. Milrinone was shown to have bidirectional effects in acute HF with an excess risk of the primary clinical end point in patients with ischemic HF and similar or decreased risk in patients with nonischemic cardiomyopathy compared with placebo.5 In a recent analysis from the Systolic Heart Failure Treatment with the I f Inhibitor Ivabradine (SHIFT) trial, every 10-mm Hg reduction in SBP was associated with an increased risk of all-cause mortality by 12% in patients with chronic HFrEF on background contemporary medical therapies.6 Patients hospitalized for worsening HFrEF even with low-normal SBP face a higher risk for adverse events. In the Organized Program to Initiate Life-saving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF) registry, patients with SBP <120 mm Hg at the time of hospital presentation experienced in-hospital and postdischarge mortality rates of 6.2% and 14.9%, respectively, compared with 1.4% and 4.7% in patients with SBP >160 mm Hg.7 In addition, symptomatic hypotensive episodes on therapy may contribute to nonadherence by patients and unwillingness by providers to optimize doses, leading to treatment failures.8,9

Blood Pressure as a Target for Drug Development
Despite afterload reduction, blood pressure lowering represents a poor target for novel HFrEF drug development. First, most patients on optimal doses of contemporary HF therapy are already facing relatively low blood pressure in the chronic setting. Second, although neurohormonal blockers are often titrated based on in-clinic vital sign assessment, 24-hour ambulatory blood pressures in these patients show substantial diurnal variation. In a small prospective study, the step-wise addition of neurohormonal agents contributed to significant daytime and especially nocturnal hypotensive episodes, which were associated with an increase in cardiovascular events, despite stable pre- and post-treatment in-clinic blood pressure measurements.10 Patients on angiotensin-converting
enzyme inhibitors (ACEi) or ARBs are at increased risk of nocturnal hypotension because angiotensin-II is an important factor in maintaining systemic blood pressure. Recent data from Heart Failure Endpoint Evaluation of Angiotensin II Antagonist Losartan (HEAAL) revealed that visit-to-visit variability in blood pressure measurements were common in ambulatory patients with HFpEF and were associated with increased death or HF hospitalization. Third, even in well-monitored clinical trials, there is a disconnect between symptoms of reduced cerebral perfusion and measured blood pressures. Indeed, blood pressures in contemporary HFpEF trials have been largely unchanged despite the step-wise addition of hemodynamically active agents and variable rates of hypotension (Table 1). This may reflect variability and lack of standardization in the definitions used for adverse events related to hypotension and inconsistencies in blood pressure monitoring in clinical trials. For instance, in the Beta-Blocker Evaluation of Survival Trial (BEST) trial, rates of dizziness were 39%, hypotension 20%, syncope 10%, and postural hypotension 9%. Finally, although maximally tolerated doses of hemodynamically active agents are often desired in practice, the efficacy of these agents is not consistently linked to reductions in SBP. For instance, in the Prospective Comparison of ARNI With ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial, SBP trajectory as a time-varying covariate was not a determinant of benefit of sacubitril/valsartan compared with enalapril.

§Includes nitrates and other vasodilators.
Hypotension—A Major Clinical Trial Roadblock

Several converging lines of evidence support reassessment of our current model of neurohormonal modulation. First, there are variable incremental benefits seen with more complete renin–angiotensin–aldosterone system blockade with higher dose ACEi (compared with lower dose) or the addition of ARBs and direct renin inhibitors (to ACEi, β-blockers, and mineralocorticoid receptor antagonists). Second, there has not been net clinical benefit of adjunctive blockade of alternative neurohormonal or cytokine pathways. Failures of these drug development programs may be driven by diminishing marginal efficacy because of saturation of available neurohormonal targets.

However, risk of hypotension with increasing neurohormonal blockade represents a major concern and was commonly observed in many of these chronic HF trials. Indeed, multiple HF trials have failed or experienced significant setbacks due to adverse therapy-related hemodynamic effects. Hypotension may manifest by 2 potential mechanisms: (1) direct therapy-related vasodilation or (2) volume depletion with improvement in myocardial function and reduction in diuretic requirement over time. Mak et al have demonstrated that patients who experience hypotensive episodes after addition of ACEi, ARB, or β-blockers are at higher risk for subsequent HF readmissions and composite all-cause mortality and readmissions. Thus, therapy-related hemodynamic perturbations may have contributed to the inverse-J relationship between intensity of neurohormonal modulation and event rates (Figure). Moreover, it is well known that intolerance to these medications in patients with advanced HF is a marker of poor prognosis, and hence, the patients most in need of therapy are often the ones who cannot tolerate these hemodynamically active agents.

The deleterious effects of hypotension are perhaps best highlighted in acute HF trials (Table 2). Low baseline and post-treatment blood pressures have significantly limited the development of intravenous, hemodynamically active agents in early and late phases of evaluation. In this setting, hypotension is commonly observed, well-documented, and may lead to adverse outcomes, even if occurring transiently during drug administration. Patients admitted or evaluated for worsening chronic HF may be particularly susceptible to hypotension and its attendant adverse effects as a result of rapidly changing clinical status, elevated left ventricular filling pressures, and concurrent administration of vasoactive agents. In the Randomized Evaluation of Intravenous Levosimendan Efficacy (REVIVE) program, any occurrence of hypotension was the most frequent adverse event observed (50.2% in levo-simendan group; 36.4% in placebo group), occurred primarily during the first 24-hours of infusion, and represented the most common reason for drug withdrawal. Levosimendan-related risk of death (compared with placebo) after 14 days varied by baseline SBP; the relative risk of death was 1.9 in patients with SBP <100 mm Hg and 1.1 in patients with SBP ≥100 mm Hg. Hypotension related to intravenously dosed agents occurs despite careful in-hospital titration. More recent trials in acute HF, including Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure (ASCEND-HF), have excluded patients with normal or low baseline blood pressure and those concomitantly being administered vasoactive agents. Relaxin in Acute Heart Failure (RELAX-AHF) used strict hemodynamic enrollment criteria that enriched the trial population with primarily normal or hypertensive patients with an average blood pressure at enrollment of 142/82 mm Hg. Despite this, significant transient reductions in blood pressure were observed during infusion requiring in-hospital dosing adjustments in 29% of patients and withdrawal from the study protocol in 19% of patients randomized to serelaxin.

Success of Established Therapies

Hypotension is an attendant risk of drug therapy even in successful trial programs of oral therapies in chronic HF (Table 1). Although overt and persistent hypotensive episodes requiring drug discontinuation are infrequently observed in trials, rates of clinical or subclinical hypotension approach 10%. Contemporary clinical trials use various strategies that limit the incidence of hypotensive episodes compared with real-world clinical practice. First, exclusion criteria at enrollment restrict patients with baseline lower SBP. Second, early trials initiated and titrated hemodynamically active oral agents in the in-hospital setting to allow for close monitoring. This period of intensive observation and stabilization is rarely mirrored in clinical practice. Third, the use of run-in periods confounds the real-world risks of hypotension. In Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS), early detection of symptomatic hypotension led to revision of the trial protocol and 12% of patients ultimately required withdrawal before receiving the full dose study drug. Similarly, 2.2% of patients were excluded from entering the Studies of Left Ventricular Dysfunction (SOLVD) program because of symptomatic hypotension. Even more recent trials, such as PARADIGM-HF, have used run-in periods to diminish the risk of hemodynamic perturbations on drug therapy. Patients ultimately randomized had to demonstrate stability and tolerance of both enalapril and sacubitril/valsartan. Finally, there has been a recent trend toward trials with larger numbers of enrolled patients with earlier stage
disease, and certain high-risk groups for adverse events are not well represented, limiting the trials’ ability to ensure drug safety in the sickest patients. For example, in PARADIGM-HF, which is the largest chronic HFrEF trial conducted to date, elderly patients and those with functional class III or IV were relatively under-represented.

Despite their potential hemodynamic effects, certain successful drugs actually improve blood pressure profile over time secondary to improving cardiac mechanics and function. Many successful HFrEF vasoactive agents may exert heterogeneous blood pressure–lowering effects, such that deleterious hypotensive effects may be limited to select clinical subgroups including patients, for example, those with advanced age, coronary artery disease, renal dysfunction, and poor functional status. Although omapatrilat did not reduce mortality or hospitalization risk compared with enalapril in the overall Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE) trial, post hoc analysis supported clinical benefit of omapatrilat in the subgroup with higher blood pressure. Consistently, despite the robust net clinical benefits of sacubitril/valsartan in PARADIGM-HF, interaction analyses suggested reduced drug efficacy in patients with New York Heart Association class III and IV (albeit enrolled in small numbers to draw definitive conclusions). Similarly, underlying comorbid disease burden and etiology of cardiomyopathy may modify the risk of treatment-related outcomes in HF trials. In sum, select clinical benefits observed with add-on neurohormonal blockade may be balanced or even neutralized by adverse risks of hypotension.

### Future of HF Drug Development

Neurohormonal blockade and hemodynamically active agents have historically been successful in reducing morbidity and mortality in HFrEF. Saturation of available peripheral neurohormonal targets and adverse hemodynamic risks with such agents, however, have hindered the progress of contemporary drug development in HFrEF. Treatment-related hypotension is a real risk observed in both clinical and research settings, limiting optimization of disease-modifying HF therapies in patients who most need them. Unfortunately, clinical trials may underestimate the real-world risk of hypotension because currently used tools are relatively insensitive to therapy-related hemodynamic disturbances, and high-risk patients with low baseline blood pressures are categorically excluded from many studies.

So, what can be done to improve the detection and avoidance of therapy-related hypotension? First, future HF clinical trials should use standardized definitions of hypotension, preferably leveraging the use of ambulatory blood pressure monitoring to capture diurnal variation. This seems to be feasible.
as recent chronic HFrEF trials have successfully used 24-hour ambulatory heart-rate monitoring. Second, robust phase II programs are required to ensure hemodynamic safety across a range of selected doses. Third, more definitive studies should routinely include vulnerable populations that may experience adverse hemodynamic events at increased frequency. The risk of untoward drug-related hypotension may be diminished with more careful titration of vasoactive therapies in these high-risk subgroups to more lenient blood pressure targets. Trial protocols should specify and tailor dosing changes of hemodynamically active agents based on age, baseline blood pressure, and presence of obstructive coronary artery disease or chronic kidney disease. Fourth, clinicians and care teams should be trained in frequent and close monitoring of patients with HF to approximate practice in contemporary clinical trials, which may facilitate early adjustment of HF therapies in response to hemodynamic perturbations. The routine measurement of orthostatic vital signs may increase the detection of therapy-related hypotension.

Finally, new paradigms of drug development need to be forged to refocus treatment of HF with reduced and preserved ejection fraction on the heart as a primary target for therapy. In order to achieve this, therapeutic strategies should directly aim to attenuate adverse cardiac remodeling by targeting abnormalities in the non- or hypo-contractile myocyte (eg mitochondria), microcirculation, interstitium, or metabolic pathways. The safe amelioration of these components may result in improvement in clinical outcomes in HF without undue hemodynamic consequences. Newer agents under development such as mitochondria-targeting peptides, partial adenosine A1 receptor agonists, and chiasma inhibitors appear to be hemodynamically neutral (limited effects on systemic blood pressure and heart rate), and possess attributes that improve various aspects of cardiac remodeling. The development of novel therapies intended to exclusively attenuate peripheral, neurohormonal systems, in the background of already available therapies, is unlikely to produce incremental benefit and may cause excess risk related to hypotension.
