Abstract

**Background**—Junctophilin-2 (JPH2), a protein expressed in the junctional membrane complex, is necessary for proper intracellular calcium (Ca^{2+}) signaling in cardiac myocytes. Down-regulation of JPH2 expression in a model of cardiac hypertrophy was recently associated with defective coupling between plasmalemmal L-type Ca^{2+} channels and sarcoplasmic reticular ryanodine receptors. However, it remains unclear whether JPH2 expression is altered in patients with hypertrophic cardiomyopathy (HCM). In addition, the effects of down-regulation of JPH2 expression on intracellular Ca^{2+}-handling are presently poorly understood. We sought to determine whether loss of JPH2 expression is noted among patients with HCM and whether expression silencing might perturb Ca^{2+}-handling in a pro-hypertrophic manner.

**Methods and Results**—JPH2 expression was reduced in flash frozen human cardiac tissue procured from patients with HCM compared to ostensibly healthy traumatic death victims. Partial silencing of JPH2 expression in HL-1 cells by a small interfering RNA probe targeted to murine JPH2 mRNA (shJPH2) resulted in myocyte hypertrophy and increased expression of known markers of cardiac hypertrophy. While expression levels of major Ca^{2+}-handling proteins were unchanged, shJPH2 cells demonstrated depressed maximal Ca^{2+} transient amplitudes that were insensitive to LTCC activation with JPH2 knock-down. Further, reduced caffeine-triggered SR store Ca^{2+} levels were observed with potentially increased total Ca^{2+} stores. Spontaneous Ca^{2+} oscillations were elicited at a higher extracellular [Ca^{2+}] and with decreased frequency in JPH2 knock-down cells.

**Conclusions**—Our results show that JPH2 levels are reduced in patients with HCM. Reduced JPH2 expression results in reduced excitation-contraction coupling gain as well as altered Ca^{2+} homeostasis which may be associated with pro-hypertrophic remodeling.

**Key Words:** JPH2, junctophilin, hypertrophic cardiomyopathy, calcium, ryanodine receptor
Non-Standard Abbreviations and Acronyms: CAV3, caveolin type 3; CICR, calcium-induced calcium-release; e-c, excitation-contraction; HCM, hypertrophic cardiomyopathy; IP3R, inositol 1,4,5-triphosphate receptor; JPH, junctophilin; LTCC, L-type calcium channel; NCX1, sodium-calcium exchanger; MORN, membrane occupation and recognition nexus; MYBPC3, cardiac myosin binding protein; MYH7, β myosin heavy chain; RyR2, ryanodine receptor type 2; SERCA2, sarcoplasmic reticulum calcium ATPase; shRNA, short hairpin RNA; SR, sarcoplasmic reticulum; TRPC3, transient receptor potential protein type 3
Junctophilins are members of a family of proteins found in all excitable cells from striated muscle to neurons that bridge the subcellular space between the plasma membrane and the sarco/endoplasmic reticulum (SR/ER). In cardiac tissue, JPH2-encoded junctophilin type 2 (JPH2) plays a critical role in maintaining effective calcium (Ca\textsuperscript{2+}) flux\textsuperscript{1,2}. In cardiocytes, voltage-gated L-type Ca\textsuperscript{2+} channels (LTCC) at the sarcolemma allow for an influx of extracellular Ca\textsuperscript{2+}, which triggers Ca\textsuperscript{2+} release from the SR via intracellular Ca\textsuperscript{2+} release channels known as ryanodine receptors (RyR2). This process, known as Ca\textsuperscript{2+}-induced Ca\textsuperscript{2+}-release (CICR), regulates myocyte contraction. Contraction is terminated, and relaxation is initiated, by uptake of cytosolic Ca\textsuperscript{2+} back into the SR through the action of the SR Ca\textsuperscript{2+} ATPase (SERCA2) or transport into the extracellular space by the sodium-calcium exchanger (NCX1). A growing body of evidence suggests that defects in the communication between LTCC and RyR2 play a central role in the development of hypertrophic cardiomyopathy (HCM) and heart failure\textsuperscript{3-5}.

HCM, defined as unexplained cardiac hypertrophy, affects approximately 1 in 500 persons and is one of the most common genetic cardiovascular diseases\textsuperscript{6}. In addition, HCM is the most common cause of sudden cardiac arrest in young athletes and a significant cause of sudden death in the young in general\textsuperscript{7,8}. Classically, HCM is viewed as a disease of the cardiac sarcomere whereby mutations in the genes encoding key sarcomeric proteins of the heart, such as MYH7-encoded β-myosin heavy chain (MYH7) and MYBPC3-encoded cardiac myosin binding protein C (MYBPC3), cause pathological cardiac hypertrophy. While the pathogenesis of HCM may be initiated with a genetic mutation, emerging evidence has associated gain-of-function disruptions in Ca\textsuperscript{2+} homeostasis which increase intracellular Ca\textsuperscript{2+} levels with induction of a pro-hypertrophic response. Increased Ca\textsuperscript{2+} release from the SR, either through impaired inhibition of RyR2 function, or increased expression and function of SR inositol 1,4,5-trisphosphate receptors...
(IP3Rs), have been associated with cardiac hypertrophy\textsuperscript{9,10}. Further, activation of IP3Rs in the nuclear envelope and increased store-operated Ca\textsuperscript{2+} entry through the transient receptor potential protein TRPC3 can similarly lead to cardiac enlargement in animal models\textsuperscript{11,12}. In some patients with HCM, unabated disease progression results in further pathogenic remodeling ultimately leading to heart failure with loss of contractility\textsuperscript{13}.

Heart failure is one of the major causes of morbidity and mortality in the US as well as the world\textsuperscript{14}. Depressed contractility, particularly rate-dependent contractility reserve, is a common feature of a failing myocyte, and several lines of evidence point to an underlying defect in Ca\textsuperscript{2+}-handling\textsuperscript{15}. Compared to gain-of-function defects in HCM, failure generally demonstrates a loss-of-function defect in CICR, prolonged transient duration, and increased basal Ca\textsuperscript{2+} levels\textsuperscript{16}. Loss of CICR is likely due to uncoupling of RyR2 from the LTCC, either functionally or physically, resulting in an orphaned RyR2 which has reduced sensitivity to Ca\textsuperscript{2+} entry from the LTCC\textsuperscript{4}. This is reflected in a loss of excitation-contraction (e-c) coupling gain, such that the same influx of extracellular Ca\textsuperscript{2+} produces a reduced RyR2-mediated Ca\textsuperscript{2+} transient\textsuperscript{17,18}. Despite the apparent dichotomous association of gain-of-function Ca\textsuperscript{2+} defects in HCM and loss-of-function Ca\textsuperscript{2+} defects in heart failure, there is evidence for overlapping Ca\textsuperscript{2+} perturbations between the disease states.

JPH2, the major cardiac junctophilin isoform, is necessary for the critical approximation of the LTCC with the RyR2 in the dyad\textsuperscript{19,20}. Amino-terminal membrane occupation and recognition nexus (MORN) motifs interact with the sarcolemma, while a carboxy-terminal transmembrane domain tethers the opposite end to the SR. The critical role of this protein in maintaining the precise sub-sarcolemmal geometry needed for CICR is underscored by the embryonic lethality of JPH2-deficient mice stemming from altered dyadic ultrastructure and
stochastic Ca\textsuperscript{2+} transients with reduced amplitude\textsuperscript{19}. Loss of JPH2 expression was observed in rodent models of HCM and heart failure and is present during an early stage of dyadic “intermolecular failure”\textsuperscript{21,22}. In skeletal muscle, JPH expression silencing resulted in loss of triadic ultrastructure and reduced CICR amplitude\textsuperscript{23}. Recently, we identified three patients with HCM hosting mutations in \textit{JPH2}, over-expression of which reduced CICR and disrupted cellular ultrastructure\textsuperscript{24}.

To this end, we sought to determine whether a loss of JPH2 protein expression is found in human HCM, and to determine the effect of \textit{JPH2} gene silencing on Ca\textsuperscript{2+}-handling within the cardiocyte. We demonstrate reduced JPH2 expression in patients with HCM as well as increased HL-1 cell size and up-regulation of the pro-hypertrophic gene program with expression silencing. Further, our observation that maximal Ca\textsuperscript{2+} transient, caffeine-stimulated store Ca\textsuperscript{2+}-release, and spontaneous transients at low extracellular Ca\textsuperscript{2+} levels were each reduced supporting a conclusion that JPH2 knock-down may result in reduced e-c coupling through uncoupled RyR2 and LTCC.

**Methods**

**Human Cardiac Tissue**

Human cardiac tissue was obtained from the left ventricle of traumatic death victims with no structural heart disease (BioChain Institute, CA; P1234139, Lot A506041; P1234138, Lot A710149; and CP-R01-T1234130, Lot B201244). Left ventricular myectomy tissue samples from patients with HCM were obtained according to protocols approved by the Mayo Foundation Institutional Review Board following informed consent. Immediately upon surgical resection, tissue samples were flash frozen in liquid nitrogen and stored at -80\textdegree C. Each HCM
specimen was genotyped comprehensively for mutations in MYH7, MYBPC3, MYL2-encoded regulatory myosin light chain, MYL3-encoded essential myosin light chain, TNNT3-encoded troponin I, TPM1-encoded alpha-tropomyosin, TNNT2-encoded troponin T, and ACTC-encoded alpha-cardiac actin to determine the genetic substrate for HCM pathogenesis using previously outlined methods\textsuperscript{25}. While not equivalent to the clinical genetic testing panel, these genes contain the majority of HCM-associated mutations.

**Western Blot**

Western blot analysis on whole protein lysates was conducted as previously described\textsuperscript{25}. Briefly, reduced lysates were resolved by SDS-polyacrylamide gel electrophoresis (4-15\% for JPH2, CAV3, GAPDH; 6\% for RyR2; 7.5\% for LTCC; 10\% for NCX1, SERCA2; and 15\% for PLN), transferred to a nitrocellulose membrane, and blotted with appropriate primary antibodies: anti-JPH2, anti-CAV3 (generous gift from Dr. Jonathan Makielski), anti-LTCC (Alomone Labs, Jerusalem), anti-RyR2 and -PLN (Thermo Fisher Scientific, IL), anti-NCX1 (Swant, Switzerland), anti-SERCA2 (Santa Cruz Biotechnology, CA), and anti-glyceraldehyde 3-phosphate dehydrogenase (GAPDH, Millipore, CA) antibodies. After application of appropriate secondary antibody, protein was detected using chemiluminescence reagent (Perkin Elmer, MA) or developed using Alexa-Fluor680-conjugated anti-mouse (Invitrogen Molecular Probes, CA) and/or IR800Dye-conjugated anti-rabbit secondary antibodies (Rockland Immunochemicals, PA), and scanned on an Odyssey infrared scanner (Li-Cor, NE). Band density was quantified using ImageJ software\textsuperscript{26}. For human myectomy studies, samples were run unblinded to genetic mutation status and each replication Western blot utilized a different portion of the subject’s myectomy tissue.
Short Hairpin RNA Construct, Cell Culture, Transfection, Adenovirus Infection

The shRNA-encoded construct utilized for transient transfection experiments is described previously. Briefly, screening experiments for RNA interfering probes to suppress JPH transcription identified a probe which targeted a conserved region of the mRNA encoding the second MORN motif domain of JPH2 (shJPH2) and JPH1. Subsequent cloning of the oligonucleotide into the pCMS-EGFP (BD Biosciences Clontech, CA) vector, in which the GFP reporter was exchanged with DsRED2, created the transient transfection construct pCMS-shRNA.

Lipofectamine-based transfection of pCMS-shRNA maximally achieved a 1% transfection rate in our studies. While suitable for single cell analyses (cell size, Ca\textsuperscript{2+} transient and store studies) high-efficiency shRNA oligo delivery was obtained through viral transduction/infection in studies requiring 100% shRNA delivery. Adenoviral delivery of shJPH2 and shLuc was achieved by insertion of the shRNA-encoding cassette into the Dual-Basic-RFP construct prior to ligation of the shRNA-RFP expression cassettes into a shuttle vector and in vitro recombinant to Ad5 adenoviral backbone with E1/E3 deletion (Vector Biolabs, PA) creating AdX-shRNA. Virus was packaged in HEK293 cells to produce viral lysates, viral titer was measured by Adeno-X Rapid Titer Kit (Clontech Laboratories, Inc., CA), and the viral lysate was stored in 1M sucrose, 5% tertiary amine beta cyclodextrin in PBS (in mM: 137 NaCl\textsubscript{2}, 10 NaH\textsubscript{2}PO\textsubscript{4}, 2.7 KCl\textsubscript{2}, 1 KH\textsubscript{2}PO\textsubscript{4}, pH 7.4). Murine atrial tissue-derived HL-1 cells were maintained as described previously. Briefly, low passage number HL-1 cells were grown on 0.02% gelatin, 1% fibronectin coated surfaces with Claycomb media (10% FBS (Sigma, Lot 116K8400), 100U/mL pen, 100ug/mL
strep, 0.1mM norepinephrine, 2mM L-glutamine). For all confocal analysis, $5 \times 10^4$ cells were plated on 23mm diameter glass cover slip Delta TPG culture dishes (Bioptechs, PA). For Western blot analysis, $5 \times 10^5$ cells were plated on 60mm diameter plastic tissue culture dishes (Falcon). Cells were transiently transfected using GeneJammer transfection reagent (Stratagene) per manufacturer’s instructions with media replacement every 48 hours. Cells were assayed 96 hours post transfection or infection and shRNA delivery was confirmed through DsRED2 or RFP fluorescence, respectively. Prior to phenylephrine (PE) treatment, cells were maintained in Claycomb media without norepinephrine for 96 hours to ensure absence of adrenergic receptor de-sensitization. Cells were then treated with Claycomb media containing 100μM PE (Sigma) or vehicle.

**Cell Size and Calcium Measurements**

Measurements of cell size and intracellular Ca$^{2+}$ levels were performed using an Axiovert 200M-Apotome (Carl Zeiss Inc., CA) system with a rapid filter changer (Lambda DG-4, Sutter Instrument, CA), and analyzed using AxioVision v4.6 (Carl Zeiss Inc.) software. For all cell size experiments, the area of RFP-positive cells was measured by tracing the cell periphery after scaling calibration. To confirm accurate identification of the sarcolemma and accurate cell size measurements, wheat germ agglutinin (WGA, Invitrogen) diluted in Hank’s balanced salt solution (Invitrogen) was utilized to fluorescently label the sarcolemma, and cell size measurements were repeated in an independent assay. Prior to [Ca$^{2+}$] measurements, cells were washed twice with Tyrode buffer (in mM: 140 NaCl, 5 KCl, 10 HEPES, 2.5 CaCl$_2$, 2 MgCl$_2$, 10 D-glucose; pH 7.4), followed by loading for 45 min with 2.5μM Fura-2 AM or 5μM Fluo-4 AM dye (Invitrogen) prior to 15 min de-esterification in Tyrode. For Fura-2 AM studies, regular
spontaneous Ca²⁺ transients were measured via fluorescence versus time with maximal Ca²⁺
transients (Fₘₐₓ) measured as the peak fluorescence achieved relative to basal fluorescence (Fₒ).
Ratiometric 340/380nm measurements allowed for correction of intracellular dye levels and
estimation of rest/basal Ca²⁺ levels. For Fluo-4 AM studies, transients were measured via
fluorescence versus time. Transient amplitude (Fₘₐₓ/Fₒ), time to amplitude peak (Tₚₑ𝐚ᵏ), and
time to decay to 50% the maximal fluorescent intensity (T₉₅₀), and resting calcium levels (Fₒ)
were measured. Pharmacologic modulation of LTCC activity was achieved by addition of two
LTCC agonists: 10µM (S)-(-)-Bay K 8644²⁸ (BayK; Tocris Bioscience, Ellisville, MO) and
500nM FPL 64176²⁹ (FPL; Tocris Bioscience) and an LTCC antagonist: 100nM nifedipine³⁰
(Tocris Bioscience) during Fluo-4 AM de-esterification. Alteration of extracellular Ca²⁺ levels
([Ca²⁺]₀) was achieved by equilibrating cells in Tyrode buffer with no Ca²⁺ (0Ca²⁺) without
EGTA buffering for 10 minutes, and successive increases in [Ca²⁺]₀ utilized similarly prepared
Tyrode buffer with appropriate CaCl₂ concentrations.

To ascertain SR-stored Ca²⁺ levels through activation of RyR2, 10mM caffeine (Sigma)
is applied to the tyrode-immersed, Fura-2-loaded cells directly under real-time confocal
analysis. To determine store Ca²⁺ levels through an SR-independent release mechanism, cells
were treated with 10µM ionomycin (Sigma) which is a Ca²⁺ ionophore known to permeabilize
membranes allowing for free movement of Ca²⁺. Prior to ionomycin treatment, cells were
rapidly switched to 0Na⁺/0Ca²⁺ tyrode (in mM: 140 NaCl, 5 KCl, 10 HEPES, 4.5 MgCl₂, 10
EGTA, 10 D-glucose, pH 7.4) to prevent influx of extracellular Ca²⁺ with treatment as well as
alterations in cytosolic Ca²⁺ due to the action of the LTCC and the NCX1.

Quantitative Real-Time Polymerase Chain Reaction
Total RNA was extracted from HL-1 cells 96 hours after infection with AdX-shRNA using the RNasy Protect Mini Kit (Qiagen) prior to storage at -80°C. RNA integrity was confirmed by Agilent 2100 Bioanalyzer analysis prior to cDNA library genesis utilizing poly-T primer-based reverse transcription (Quanta Biosciences, MD). RNA expression levels of skeletal actin (ACTA, Mm00808218_g1), atrial natriuretic factor (ANF, Mm01255747_g1), brain natriuretic factor (BNP, Mm00435304_g1), MYH7 (Mm00600555_m1), and regulator of calcineurin 1-exon 4 splice isoform (RCAN1-4, Mm00627762_m1) were evaluated using quantitative real-time polymerase chain reaction (qRT-PCR) via TaqMan Gene Expression Assays (Applied Biosciences, CA). Detection of an interferon (IFN)-response by the cells was conducted by RNA expression levels of 2'-5' oligoadenylate synthetase 1b (OAS1, Mm00449297_m1) and signal transducer and activator of transcription 1 (STAT1, Mm00439531_m1). The threshold cycle value, representing the number of PCR cycles (C) at which a normalized reporter signal (Rn) first crosses a detection threshold, was determined. The inverse level of RNA template was calculated and normalized to endogenous GAPDH (4352932E) levels. Relative fold change in expression of AdX-shJPH was then calculated compared to AdX-shLuc treatment.

Statistics

ANOVA and t-test analysis was conducted for all studies, as appropriate, with the threshold of significance set to \( P < 0.05 \). All statistical analyses were done on at least three independent experiments and are expressed as mean ± standard error of the mean.

Results

JPH2 is Down-Regulated in Human Hypertrophic Cardiomyopathy
Previous investigations have shown JPH2 down-regulation in rodent models of HCM, dilated cardiomyopathy, pressure-induced hypertrophy, and decompensated cardiac failure\textsuperscript{21,22}. Despite these findings, little is known about the expression levels of JPH2 in human disease. Surgical myectomy to remove left ventricular septal myocardium, a treatment for obstructive HCM, provides a relatively unique means of acquiring diseased myocardium from human subjects. Given this resource, we sought to determine whether the down-regulation of JPH2 previously seen in rodent models of cardiac disease was also a characteristic of HCM in humans.

Western blot analysis of JPH2 expression levels from left ventricular protein lysates obtained from three otherwise-healthy traumatic death victims were compared to protein lysates obtained from 11 patients with HCM. Five were acquired from patients with mutations in \textit{MYH7} (hosting MYH7-G741R, -R663H, -I736T, -R403Q, and -M922K mutations from left to right lanes in Figure 1A) and three with mutations in \textit{MYBPC} (MYBPC-E258K, -L527 fs/3, and -L1258 fs/71, respectively) which represent the two most common genetic subtypes of HCM. Further, three samples obtained from probands not hosting mutations in the analyzed genes were similarly assayed. While there was some variation in JPH2 expression among presumably “healthy” subjects, a reduction in expression was observed in all samples acquired from patients with HCM. Quantification of blots taken from independent portions of resected myocardium revealed that all individuals with HCM had reduced JPH2 expression (ranging from $0.011 \pm 0.006$ to $0.343 \pm 0.089$ normalized intensity units) compared to trauma samples (from $1.536 \pm 0.331$ to $0.700 \pm 0.078$) as depicted in (Figure 1B). When taken as a whole, HCM samples had a mean relative JPH2 expression of $0.120 \pm 0.022$ compared to ostensibly healthy tissue ($1.079 \pm 0.638$, $P < 0.0001$; Figure 1B, inset).
**shJPH2 Achieves Durable Expression Knock-Down**

Given the reduction of JPH2 protein expression in human HCM, we sought to determine whether this phenomenon was a compensatory physiologic response of the heart or whether it represents a potential initiating factor in hypertrophic remodeling. To address this, interfering RNA targeted to JPH2 mRNA was introduced into HL-1 cells which express endogenous JPH2 as well as all critical cellular components necessary for cardiac excitation contraction coupling, including RyR2, LTCC, SERCA2, NCX1, and the β-adrenergic receptor. These cells demonstrate spontaneous CICR and have been used previously to characterize the effect of genetic mutations in RyR2 function. Previous studies utilizing this shRNA probe have demonstrated a significant reduction in the expression levels of JPH1 as well as JPH2 in skeletal muscle; however, HL-1 cells do not express JPH1 by qRT-PCR (Figure 2A), leaving JPH2 as the only junctophilin family member silenced by expression of this shRNA.

Utilizing the RFP marker co-expressed by the adenovirus, we achieved nearly 100% infectivity of the HL-1 cells with a multiplicity of infection of 100IFU/cell (data not shown). As shown in Figure 2B & C, adenoviral delivery of the shJPH2 probe demonstrated a sustained JPH2 expression knock-down of 26.5% after 96 hours when normalized to GAPDH expression relative to shLuc ($P < 0.01$). The expression of caveolin-3 (CAV3), a JPH2 binding partner, was not affected by JPH2 silencing.

Expression of double stranded RNA in mammalian cells may induce a type 1 IFN response that induces global alterations to multiple cellular processes which may confound the effect of JPH2 expression silencing. To ensure that such a response was not present with adenoviral delivery of AdX-shJPH2 and shLuc, and to test this known cardiac remodeling signaling cascade, RNA expression levels of IFN-induced OAS1 and STAT1 were determined.
by qRT-PCR. As demonstrated in Figure 2D, there was no alteration in OAS1 and STAT1 levels in HL-1 cells treated with AdX-shJPH2 relative to AdX-shLuc normalized to GAPDH expression.

**JPH2 Knock-Down Increases Cell Size and Induces Pro-Hypertrophic Marker Expression**

To determine whether an acute suppression of JPH2 expression is sufficient to initiate cardiac hypertrophic remodeling, HL-1 cell area was measured after both transient transfection and adenoviral infection of shJPH2. In pCMS-JPH2 transfected cells, partial JPH2 expression silencing resulted in a marked increase in HL-1 cellular size of 75.3 ± 7.5% (N = 68) when compared to control shLuc cells (N = 245; P < 0.0001). To confirm accuracy of cell size measurements, we fluorescently labeled the cell sarcolemma with WGA (Figure 3A) and confirmed an increase in cellular size of 57.0 ± 14.0% (N = 59) when compared to control (N = 80; P = 0.004) which was not statistically significantly different from the degree of hypertrophy seen without WGA-labeling (P = 0.2). Similarly, adenoviral delivery of shJPH2 resulted in an increase of 94.2 ± 7.3%, N = 346, when compared to AdX-shLuc (N = 469; P < 0.0001) which was not statistically significantly between transfection delivery of shJPH2 (P = 0.3; Figure 3B).

As a positive control, a known pharmacologic inducer of hypertrophy in this cell line, PE, was applied (Figure 3B, light gray bars). Treatment of these cells with an α1 adrenergic receptor agonist initiated a similar hypertrophic response (increase of 75.4 ± 7.9%, N = 485) relative to vehicle treated cells (N = 657; P < 0.0001) when compared to shJPH2 expression silencing.

As many potential pathways could contribute to increased cellular size *in vitro*, we attempted to correlate this observation with molecular markers of the well-established cardiac hypertrophic remodeling process. QRT-PCR was conducted on cells infected with AdX-shRNA
to test for induction of several known markers of pathologic hypertrophy. As shown in Figure 3C, a significant increase in ACTA (12.8 ± 5.6%), ANF (10.6 ± 4.4%), BNP (17.9 ± 5.0%), and MYH7 (26.4 ± 9.1%) was observed in AdX-shJPH2 cells compared to control cells (P < 0.05). Furthermore, we tested transcriptional expression of RCAN1-4, a marker of calcineurin-dependent signaling which is one potential mediator of remodeling in the cardiocyte. In AdX-shJPH2 infected cells, there was no increase in RCAN1-4 expression levels by qRT-PCR.

**JPH2 Knock-Down Perturbs Calcium Flux and Homeostasis**

Based on the observation of increased cellular area as well as transcriptional up-regulation of pro-hypertrophic markers in the cells, we explored the possibility that Ca\(^{2+}\) dysregulation may be associated with JPH2 expression knock-down. Alterations in Ca\(^{2+}\) transients and basal Ca\(^{2+}\) levels have been linked to both the initiation of hypertrophy as well as arrhythmogenesis in the heart. HL-1 cells spontaneously and regularly oscillate Ca\(^{2+}\) through the action of excitation-contraction coupling proteins. We have previously utilized HL-1 cells to measure Ca\(^{2+}\)-transient amplitude, and the firm adherence of these cells to the growth surface is suitable for maintaining real-time confocal measurements during pharmacological treatment\(^{24}\).

Maximal Ca\(^{2+}\) transients achievable were significantly reduced in cells transiently transfected with pCMS-shJPH2 (1.10 ± 0.09, \(N = 69\)) when compared to control cells (1.60 ± 0.03, \(N = 126; P < 0.0001\)) as demonstrated in Figure 4A & 4B. This reduction in transient amplitude was insensitive to pharmacological stimulation of the LTCC. While BayK and FPL, two LTCC stimulators, increased control cell transient amplitudes (1.75 ± 0.07, \(N = 43; P = 0.008\) and 1.88 ± 0.07, \(N = 53; P < 0.0001\) versus untreated control cells, respectively), this increase was not seen in shJPH2 cells (Bay K: 1.20 ± 0.04, \(N = 43\) and FPL: 1.14 ± 0.03, \(N = \))
which demonstrated transient amplitudes that were not significantly different from untreated shJPH2 cells (Figure 4B). Conversely, application of nifedipine reduced Ca^{2+} transient amplitude in control cells (1.14 ± 0.03, N = 52; P < 0.0001 versus untreated control cells), while there was no statistically significant difference between nifedipine-treated shJPH2 cells (1.06 ± 0.02, N = 28) and untreated cells (P = 0.5, Figure 4B).

In addition to reductions in transient amplitude, transient kinetics were altered with JPH2 knock-down. While the time to transient peak was unchanged, the time for the Ca^{2+}-transient to decay was reduced in shJPH2 cells (508 ± 46ms, N = 49) compared to control cells (888 ± 49ms, N = 119, Figure 4C & 4D). Despite impaired Ca^{2+} transient amplitude, the resting Fura-2 AM fluorescence was higher in cells with shJPH2 (0.63 ± 0.03, N = 64) compared to control (0.55 ± 0.04, N = 47), although this finding was not statistically significant (P = 0.06, Figure 4E).

**JPH2 Knock-Down Alters Store Calcium Levels**

To determine whether the reduction in Ca^{2+} transient and potential alteration in basal Ca^{2+} levels were due to alterations in store Ca^{2+}, caffeine was applied to measure SR store Ca^{2+} levels. As demonstrated in Figure 5A & 5B, HL-1 cells transiently transfected with pCMS-shJPH2 had a significantly lower caffeine-induced Ca^{2+} release (0.82 ± 0.07, N = 25) compared to control (1.06 ± 0.05, N = 48; P < 0.0001). To determine whether this apparent loss of store Ca^{2+} was due to alterations in the SR Ca^{2+} store levels in isolation or whether other Ca^{2+} stores are similarly altered, ionomycin was applied. As demonstrated in Figure 5C & 5D, under 0Na^{+}/0Ca^{2+} buffer conditions, ionomycin treatment resulted in release of store Ca^{2+} which was greater in the pCMS-shJPH2 transfected cells (1.84 ± 0.10, N = 27) compared to controls (1.35 ±
0.06, N = 75; \( P < 0.0001 \). Thus, despite an overloaded total Ca\(^{2+}\) store in the shJPH2 cells, there was a significant reduction in caffeine-mediated SR store levels.

**JPH2 Knock-Down Suppresses Spontaneous Calcium Oscillations**

The HL-1 cell line demonstrates regular spontaneous Ca\(^{2+}\) oscillations under normal extracellular [Ca\(^{2+}\)]. Based on the previously observed loss of Ca\(^{2+}\) transient amplitude and insensitivity of the Ca\(^{2+}\) transient to LTCC stimulation with JPH2 expression silencing, we next tested the coupling of spontaneous Ca\(^{2+}\) transients generation with extracellular [Ca\(^{2+}\)]. As demonstrated in Figure 6A, AdX-shLuc cells in 0Ca\(^{2+}\) buffer generate no regular Ca\(^{2+}\) oscillations and occasionally demonstrate stochastic transients which are presumably not LTCC-triggered Ca\(^{2+}\) release events. With addition of 0.1 and 0.25mM [Ca\(^{2+}\)], the stochastic, non-LTCC-mediated transients begin to yield regular oscillations which are coordinated among the cells. Application of 1 and 2.5mM [Ca\(^{2+}\)] induced regular oscillations which are spontaneous and are simultaneously triggered in nearly every cell in each field. In contrast, knock-down AdX-shJPH2 infected HL-1 cells do not demonstrate Ca\(^{2+}\) oscillations until 1mM [Ca\(^{2+}\)]. This is quantified in Figure 6B, in which there is a blunting of Ca\(^{2+}\) oscillation generation with JPH2 silencing with 0.1 and 0.25mM [Ca\(^{2+}\)]. This is reflected in a lower proportion of oscillating cells infected with AdX-shJPH2 than control at 0.1mM (0.04 \pm 0.01%, N = 12 fields versus 0.13 \pm 0.02%, N = 12; \( P = 0.002 \)) and 2.5mM (0.05 \pm 0.05%, N = 13 versus 0.38 \pm 0.01%, N = 11; \( P = 0.009 \)). Further, while there is no difference in the number of field-wide Ca\(^{2+}\) oscillations per time at lower [Ca\(^{2+}\)] levels, there is a significant reduction in the oscillation frequency in cells infected with shJPH2 (7.7 \pm 1.2 transients/30s, N = 15 fields) than shLuc (17.0 \pm 4.3, N = 11 fields; \( P = 0.02 \)) at 2.5mM [Ca\(^{2+}\)] (Figure 6C).
JPH2 Knock-Down Does Not Alter Calcium-Handling Protein Expression

Due to the observed reduction in Ca$^{2+}$ transient amplitude, altered transient kinetics, and perturbed store Ca$^{2+}$ levels, we next explore the expression levels of multiple proteins necessary for effective e-c coupling and transient formation (Figure 7). Despite the reduction of CICR amplitude, western blot analysis of LTCC and RyR2 consistently revealed no change in expression with AdX-shJPH2-treated cells. Further, there was not a statistically significant change in expression of NCX1, SERCA2 and PLN in JPH2 knock-down cells compared to controls.

Discussion

The junctophilin family of proteins are critical for proper Ca$^{2+}$ flux and homeostasis in excitable cells including skeletal muscle (JPH1 and 2\textsuperscript{37,38}), cardiac muscle (JPH2), and neuronal tissue (JPH3 and 4\textsuperscript{39-41}). In concert with the recent insight into the cellular role of these proteins, genetic mutations which perturb the function of JPH2 and JPH3 have been associated with the pathogenesis of human disease. While its pathogenic mechanism remains elusive, a CAG/CTG nucleotide repeat expansion in a potential alternatively-spliced exon of \textit{JPH3}-encoded junctophilin type 3 has been associated with Huntington disease type 2 in humans\textsuperscript{42}. Further, we recently demonstrated three missense mutations in a cohort of 388 patients with HCM that were mutation negative for the traditional HCM-associated sarcomeric protein genes\textsuperscript{24}. Based upon the emerging role of JPH dysregulation and dysfunction, we sought to understand how reduced expression of JPH2 might play a role in cardiomyopathy.
Herein, we demonstrated that myocardium from HCM patients demonstrate a significant reduction in JPH2 expression independent of underlying disease-causing genotype and may reflect a common feature in the cardiomyopathic remodeling of this disease. This fits well with the previous observations that reduction of JPH2 levels occurs across a relatively diverse range of rodent cardiomyopathic disease states. The generalizability of this phenomena in human heart failure, pressure (hypertension)-induced hypertrophy, or myopathic sequelae of organic disease states such as idiopathic cardiomyopathy of diabetes, is an unanswered question. It is also possible that the down-regulation of JPH2 is not a property of other mechanisms of cardiac hypertrophy.

In order to test whether this reduction of JPH2 expression is sufficient to induce cardiac dysfunction and hypertrophy, we used a RNA silencing probe to knock-down JPH2 expression. Our observation that interfering RNA silencing of endogenous JPH2 results in a marked increase in cellular size, potentially through further induction of the fetal gene program, are evidence that even relatively small reductions in JPH2 expression can be an initiating factor in the pathogenic remodeling of the heart and not simply an adaptive response with no pathophysiologic consequence. In experiments using native cardiac tissue, up-regulation of ACTA, ANF, BNP, and MYH7 as transcriptional markers of the pro-hypertrophic cellular response are on a fold-scale that is greater than the 10-30% increase we observe. As the HL-1 cells are immortalized and perpetually grow and divide, it is possible that there is a higher basal level of these transcripts within the transcriptional milieu of the cell, and we are observing a relative modest increase in a highly active pro-growth/hypertrophic gene program. Alternatively, it is possible that the observed increase in cell size seen may not be solely mediated through the traditional hypertrophic response of which these transcripts are markers.
Silencing of JPH2 in HL-1 cells resulted in significant alterations in both basal and dynamic Ca\(^{2+}\) signaling within the cell. Our observations that JPH2 expression silencing results in reduced CICR through a reduction in the maximal transient amplitude without alteration of LTCC, RyR2, SERCA2, PLN, or NCX1 expression supports a role for JPH2 in maintaining effective e-c coupling gain. This closely follows our previous work in which functional characterization of the three HCM-associated mutations demonstrated similar decrease in CICR amplitude when expressed in HL-1 cells\(^{24}\) and the reduced CICR seen in skeletal muscle with JPH1 and 2 knock-down\(^{23}\). When Ca\(^{2+}\) is titrated into the extracellular buffer of spontaneously oscillating HL-1 cells, JPH2 knock-down reduces the sensitivity of CICR to extracellular Ca\(^{2+}\). While RyR2-mediated Ca\(^{2+}\) transients are clearly present at 0.25mM [Ca\(^{2+}\)]\(_{o}\) with control shLuc-infected cells, no Ca\(^{2+}\) oscillations are seen in the shJPH2-infected cells. Since the cells did not demonstrate Ca\(^{2+}\) oscillations in 0Ca\(^{2+}\) extracellular buffer and at 2.5mM [Ca\(^{2+}\)]\(_{o}\), all cells regularly and uniformly oscillated in unison, extracellular Ca\(^{2+}\) entry through the voltage-sensitive LTCC is likely triggering the observed transients. Thus, it may be that the observed right shift in the dose-response curve with JPH2 knock-down is due to a loss of e-c coupling gain such that more Ca\(^{2+}\) entry into the sub-sarcolemmal space is needed to trigger sufficient RyR2 opening to cause CICR. This possibility is supported by the relative insensitivity of JPH2 knock-down cells Ca\(^{2+}\) transients to LTCC activation.

These loss-of-function defects in Ca\(^{2+}\)-handling would generally reflect those seen in patients and experimental models of heart failure. Indeed, the loss of CICR amplitude, potential blunting of e-c coupling gain, and the observed reduction in SR store Ca\(^{2+}\) by caffeine-stimulation would fit with several previous models of heart failure such as rats\(^{4}\), dogs\(^{44}\), and humans\(^{18}\). Based on these previous studies, and the known role of JPH2 in maintaining critical...
dyadic geometry, one possibility is that this reduction in CICR may be due to increased distance of RyR2 from the sarcolemmal LTCC, or otherwise disrupted cellular ultrastructure. While not directly addressed herein, this physical separation may result in a relatively Ca\(^{2+}\)-insensitive RyR2 which does not respond fully to Ca\(^{2+}\) influx from the LTCC, resulting in a loss of CICR. This possibility is supported by previous observation that over-expression of HCM-associated JPH2 mutations disrupted cellular ultrastructure\(^{24}\). In addition to observed defect in CICR, alterations in cardiac relaxation are often seen in cardiac hypertrophy and failure. Reduced SERCA2 expression is commonly seen in models of cardiac hypertrophy and failure resulting in reduced SR Ca\(^{2+}\) and increased basal cytosolic Ca\(^{2+}\)\(^{45,46}\). Our observation that SERCA2 and PLN expression are unchanged is not without precedent and may reflect variation in the way this cellular model undergoes hypertrophy with JPH2 expression silencing. While the protein levels are unchanged, it is possible that the ATPase activity of SERCA2, and the inhibitory role of PLN, are nonetheless functionally impacted by post-translational modification resulting in the observed reduction in SR Ca\(^{2+}\).

The loss of JPH2 expression in rodent models of HCM, our previous association of \textit{JPH2} mutations in human HCM, and our observation of loss of JPH2 expression in patients with HCM would seemingly run counter to a solely loss-of-function defect in CICR activity. Indeed, the development of cardiac hypertrophy has largely been associated with increases in cytosolic Ca\(^{2+}\), whereby either elevation of global or dyadic Ca\(^{2+}\) levels induce the pro-hypertrophic fetal gene program through either a calmodulin kinase II- or calcineurin-mediated pathway, among others\(^{47,48}\). In a setting of reduced CICR amplitude, we observed a strong trend toward increased basal Ca\(^{2+}\) in JPH2 knock-down cells. It is unlikely that the increase in resting Ca\(^{2+}\) is directly due to alterations in the Ca\(^{2+}\) transient kinetics as the amplitude and TD\(_{50}\) are both
reduced, it may indicate increased Ca\textsuperscript{2+} leakage of RyR2 at rest. This possibility is in agreement with previous work showing that RyR2 mutations which disrupt the calmodulin binding which normally reduces RyR2 Ca\textsuperscript{2+} release activity, lead to induction of hypertrophy as well as extra Ca\textsuperscript{2+} oscillations which elevate cytosolic Ca\textsuperscript{2+} levels\textsuperscript{9}. While the ability of JPH2 to modulate the gating of RyR2 has not been directly demonstrated to date, skeletal muscle JPH1 modulates gating of RyR1 through a redox-sensitive direct interaction\textsuperscript{49}. Any role, either direct or indirect, that JPH2 may have in modulating RyR2 channel function, as well as the involvement of pro-hypertrophic signaling pathways, will require future study.

There are several limitations to our study. While we observe a clear reduction in JPH2 expression in HCM myectomy specimens compared to the control samples, we are unable to evaluate the possibility of regional differences in cardiac JPH2 expression. In particular, we are unable to ensure that the control samples were obtained from the same region of the left ventricular myocardium as the HCM myectomy specimens. In addition, while the HL-1 cell line has proven useful for our analysis, the immortalized nature of these cells, and loss of native cardiocyte shape and t-tubular ultrastructure limits our analysis and prevents direct measurement of the intermolecular coupling of dyadic proteins. Further, we are unable to determine how knock-down of JPH2 expression might affect the beating heart \textit{in vivo} and whether important hallmarks of cardiac remodeling, such as fibrous replacement of myocardium in heart failure, might be present. Future studies will need to be done to further elucidate any potential role JPH2 may have in modulating RyR2 function and how perturbations in this protein might predispose to Ca\textsuperscript{2+}-mediated diseases of the heart.

Figure Legends

Figure 1. JPH2 expression is decreased in humans with hypertrophic cardiomyopathy.
A. Representative Western blot of JPH2 expression levels in lysates prepared from left ventricular myocardium obtained from three healthy traumatic death victims and myectomy tissue from 11 patients with HCM genotype-positive for mutations in MYH7 (N = 5 individuals), MYBPC3 (3) or genotype-negative (3). From left to right, HCM patients hosted mutations of MYH7-G741R, -R663H, -I736T, -R403Q, -M922K and MYBPC-E258K, -L527 fs/3, and -1258 fs/71, respectively. GAPDH served as a loading control. B. Graph of relative mean band density of JPH2 expression of individuals with HCM (mean of 8 blots per individual) relative to control specimens (mean of 5 blots per individual). ‡, $P < 0.05$ versus each of the trauma samples; †, $P < 0.05$ versus two of the three trauma samples. Inset) Graph of the mean Western blot band density of all HCM specimens relative to mean control tissue band density. ***, $P < 0.0001$.

Figure 2. Adenovirus-mediated shRNA silencing of JPH2 in HL-1 cells.
A. Representative qRT-PCR plot of normalized fluorescence (Rn) intensity versus PCR cycle number (C_T) for three transcript-specific probe sets including JPH1, JPH2, and GAPDH targeted to un-treated HL-1 cDNA. B. Western blot of JPH2, CAV3, and GAPDH levels from HL-1 cells infected with AdX-shLuc and controls. C. Bar graph showing relative difference in band density of AdX-shJPH2 infected cells from independent Western blots relative to AdX-shLuc normalized to GAPDH (N = 7). **, $P < 0.01$. D. Bar graph demonstrating mean RNA
expression levels of OAS1 and STAT1 by qRT-PCR of AdX-shJPH2 infected cells relative to controls ($N = 6$ runs).

**Figure 3. JPH2 knock-down induces hypertrophy of HL-1 cells.**

A. Representative image of RFP-positive HL-1 cells infected with control pCMS-shLuc or pCMS-shJPH2 and labeled with WGA. Scale bar, 100µm. B. Bar graph showing mean HL-1 cell size transiently transfected with pCMS-shRNA (cross-hatch) or adenovirally infected with AdX-shRNA (no cross-hatch). Delivery of shJPH2 by either transient transfection or adenoviral infection (dark gray bars) induced an increase in cell size compared to controls (white bars) that was not significantly different between oligo-delivery methodologies. Light gray bars, treatment with phenylephrine (PE), induced a similar increase in cell size compared to vehicle-treated controls (V). Numbers in bar graph indicate number of cells analyzed. ***, $P < 0.0001$. C. Relative RNA expression levels of ACTA, ANF, BNP, MYH7, RCAN1-4 in HL-1 cells infected with AdX-shJPH2-RFP normalized control cells. Numbers in bar graphs indicate number of assays. *, $P < 0.05$.

**Figure 4. JPH2 knock-down reduces intracellular Ca$^{2+}$ transients.**

A. Representative Ca$^{2+}$ transient tracing of an HL-1 cell transiently transfected with pCMS-shJPH2 or shLuc measuring relative fluorescent intensity ($F_{\text{max}}/F_{0}$) versus time. B. Bar graph of the mean Ca$^{2+}$ transient amplitude in HL-1 cells transiently transfected with pCMS-shJPH2 or control. Cells were treated with LTCC activators BayK or FPL or LTCC blocker nifedipine (Nif). Numbers in bar graphs indicate number of cells analyzed. **, $P < 0.01$; ***, $P < 0.0001$. 
C, and D. Bar graph of time to transient peak and time to decay to half maximum intensity, respectively, in HL-1 cells transiently transfected with pCMS-shJPH2 or control. ***, $P < 0.0001$

E. Bar graph of the mean resting Ca$^{2+}$ levels in cells transiently transfected with pCMS-shJPH2 or control. Numbers in bar graphs indicate number of cells analyzed.

**Figure 5. Knock-down of JPH2 increased store Ca$^{2+}$ yet reduced RyR2-dependent caffeine-mediated store Ca$^{2+}$ release.**

A. Representative Ca$^{2+}$ tracing of HL-1 cell following caffeine application. B. Bar graph showing mean amplitude of Ca$^{2+}$ efflux from the SR in pCMS-shRNA-treated cells exposed to caffeine. Numbers in bar graph indicate number of cells analyzed. ***, $P < 0.0001$. C. Representative Ca$^{2+}$ tracing of HL-1 cells following ionomycin treatment. D. Bar graph showing mean amplitude of Ca$^{2+}$ efflux from all stores in pCMS-shRNA-treated cells exposed to ionomycin. Numbers in bar graph indicate number of cells analyzed. ***, $P < 0.0001$.

**Figure 6. Knock-down of JPH2 blunts generation of spontaneous Ca$^{2+}$ oscillations with modulation of extracellular Ca$^{2+}$ levels.**

A. Representative individual Ca$^{2+}$ tracings from a field of AdX-shJPH2 infected HL-1 cells with increasing levels of [Ca$^{2+}$]$_o$. B. A graph of proportion of spontaneously oscillating cells per field versus increasing [Ca$^{2+}$]$_o$ for both AdX-shJPH2 infected cells and control. **, $P < 0.01$. C. A graph of the number of field-wide spontaneous oscillations per 30 seconds versus increasing [Ca$^{2+}$]$_o$ for both AdX-shJPH2 infected cells and control. *, $P < 0.05$. 
Figure 7. Calcium-handling protein expression levels are unchanged with JPH2 knock-down.

Representative Western blots of LTCC, RyR2, NCX1, SERCA2, and PLN expression levels in lysates prepared from cells treated with AdX-shRNA. GAPDH served as a loading control.
