Abstract

**Background**—Unloading a failing heart with a left ventricular assist device (LVAD) can improve ejection fraction (EF) and left ventricular (LV) size; however, recovery with LVAD explantation is rare. We hypothesized that evaluation of myocyte contractility and biochemistry at the sarcomere level before and after LVAD may explain organ level changes.

**Methods and Results**—Paired LV tissue samples were frozen from 8 patients with nonischemic cardiomyopathy at LVAD implantation (Before LVAD) and prior to transplant (After LVAD). These were compared to 8 nonfailing hearts. Isolated skinned myocytes were purified, attached to a force transducer, and dimensions, maximal calcium saturated force (Fmax), calcium sensitivity, and myofilament cooperativity were assessed. Relative isoform abundance and phosphorylation levels of sarcomeric contractile proteins were measured. With LVAD support, the unloaded EF improved (10.0±1.0 to 25.6±11.0%, p=0.007), LV size decreased (LVIDd 7.6±1.2 to 4.9±1.4cm, p<0.001), and myocyte dimensions decreased (cross-sectional area 1247±346 to 638±254 \( \mu \)m\(^2\), p=0.001). Fmax improved after LVAD (3.6±0.9 to 7.3±1.8mN/mm\(^2\), p<0.001), but was still lower than nonfailing (7.3±1.8 vs. 17.6±1.8mN/mm\(^2\), p<0.001). An increase in troponin I (TnI) phosphorylation after LVAD was noted, but protein kinase C phosphorylation of TnI decreased. Biochemical changes of other sarcomeric proteins were not observed after LVAD.

**Conclusions**—There is significant improvement in LV and myocyte size with LVAD, but there is only partial recovery of EF and myocyte contractility. LVAD support was only associated with biochemical changes in TnI. This suggests that alternate mechanisms might contribute to contractile changes after LVAD and that additional interventions may be needed to alter biochemical remodeling of the sarcomere to further enhance myofilament and organ level recovery.

**Key Words:** mechanical circulatory support, remodeling heart failure, mechanical unloading, heart failure
Abbreviations

LVAD=left ventricular assist device, EF=ejection fraction, LV=left ventricle,
LVIDd=left ventricular internal dimension end-diastole, TnI=troponin I, HF=heart
failure, MyBPC=myosin binding protein C, TnT=troponin T, Tm=tropomyosin, MLC-2=regulatory myosin light chain, MLC-1=essential myosin light chain, PKA=protein
kinase A, PKC=protein kinase C, SD=standard deviation
The left ventricular assist device (LVAD) is a well established therapy for patients with end-stage heart failure (HF). The mechanical unloading of the left ventricle with the LVAD and the subsequent restoration of cardiac output results in improvements in HF symptoms, functional status, quality of life, and end-organ perfusion. In addition to these systemic effects, some patients undergoing LVAD support demonstrate improved function of the native left ventricle (LV), termed reverse remodeling. Such organ level improvements include decreased LV chamber size, decreased LV mass, and improved LV ejection fraction (EF)\(^1\) and have been accompanied by systemic effects such as normalization of catecholamine levels,\(^2\) natriuretic peptides levels,\(^3\) and circulating cytokines like TNF-\(\alpha\).\(^{1,4}\)

Some of these clinical markers of reverse remodeling at the organ level have also been demonstrated at the cellular and molecular level. Previous studies have noted reduction in myocyte hypertrophy\(^5,6\) as well as improvement in overall cardiac histology\(^7\) after LVAD support. Furthermore, in vitro studies have demonstrated improvements in myocardial contractile properties, restoration of adrenergic receptor density and responsiveness, and improved calcium handling with LVAD support.\(^8-11\)

As both clinical and cellular evidence suggested the plausibility of reversing end-stage disease, the concept arose that LVADs may be used as a bridge to recovery in HF patients. Indeed, this was met with great enthusiasm after a single center’s report of the successful explantation of LVADs in 11 of 15 patients with nonischemic cardiomyopathy treated with a combination of unloading with a LVAD followed by conventional HF medical therapy and the selective \(\beta_2\) adrenergic receptor agonist clenbuterol.\(^ {12} \) However, such high rates of recovery were not observed in the multi-institutional LVAD Working
Group study where only 6 of 67 patients (9%) underwent LVAD explantation for recovery.¹

At this time, the mechanisms of reverse remodeling remain poorly understood, and it appears that restoring myocardial contractility may be more complex than what had been initially considered. Therefore, we postulated that evaluation of myocyte contractility and biochemistry at the most fundamental contractile level of the heart, the sarcomere, before and after LVAD placement might reveal an explanation for this phenomenon. Our first goal was to assess sarcomeric contractile properties by measuring direct isometric forces on skinned isolated cell preparations. Second, since the cardiac sarcomeric proteins myosin binding protein C (MyBPC), troponin T (TnT), troponin I (TnI), tropomyosin (Tm), and regulatory myosin light chain (MLC-2) are known to effect contractility,¹³ we assessed whether post-translational modifications and/or other alterations in these proteins were affected with LVAD support.

Methods

Patient Selection and Tissue Acquisition

Paired LV tissue samples were collected and flash frozen from 8 patients with end-stage nonischemic cardiomyopathy at the time of LVAD implantation (Before LVAD) and prior to cardiac transplantation (After LVAD). Nonfailing control samples were obtained from 8 donor hearts that were harvested for transplant but then unused for non-cardiac reasons. The tissue obtained at the time of LVAD implantation consisted of a core sample from the LV apex – at the in-flow cannula of the LVAD. The tissue collected at the time of the cardiac transplant consisted of an analogously sized fragment
excised from the explanted heart. All tissue samples were immediately flash frozen in liquid nitrogen in the operating room (without the use of any cardioplegia solutions) and transported to a -80 °C freezer where they were stored until use. This storage method has been shown to preserve sarcomeric contractile protein phosphorylation state and also allow for the accurate assessment of the myocyte contractile parameters that are described below.14-16 The ischemia time from removal of LV tissue from the patient to freezing in liquid nitrogen for the Before LVAD samples was less than 10 seconds and for the After LVAD and Nonfailing samples was less than 10 minutes. The Colorado Multicenter Institutional Review Board approved the protocol for the collection, storage, and analysis of human tissue.

Medical records were retrospectively reviewed by a trained physician to obtain demographic and clinical data. Echocardiographic and hemodynamic data were obtained from the medical record at the time closest to before LVAD implantation (to ensure conditions reflecting the time the Before LVAD tissue was obtained) followed by the time closest to cardiac transplantation (to ensure conditions reflecting the time the After LVAD tissue was obtained). The data obtained from patients being supported with a LVAD reflect the device settings that were clinically indicated at the time for the patients, and represent the combined effects of native LV function as well as LVAD related unloading.

**Myocyte Contractility Measurements**

Details of the myocyte isolation and experimentation protocols have been previously described.14,17-19 Briefly, myocytes were purified from the frozen LV samples
by mechanical homogenization and subsequently permeabilized with 0.3% Triton X-100. The resulting suspension was placed on the stage of an inverted microscope, and in order to ensure adequate tissue quality, myocyte fragments with an organized myofibril pattern with clear sarcomeric striations were chosen for the contractility experiments. These isolated skinned myocyte fragments were then attached to a force transducer and motor and mechanical experiments were conducted. A representative photomicrograph is shown in Figure 1. The length and width of the skinned myocyte fragment were measured when it was attached to the force transducer in relaxing solution and a side view mirror was used to measure the thickness. Cross-sectional area was calculated using an elliptical approximation. The isolated myocytes were stored on ice and used within 20 hours of isolation. All experiments were performed at 15 °C and since sarcomere length can effect force measurements, the sarcomere length was set to 2.1 um for all experiments.

Myocytes were exposed in random order to six different activation solutions containing varying concentrations of calcium (pCa 9.0 to 4.5) and the developed force for each of the calcium concentrations was recorded as shown in Figure 2a. The developed force at the maximal calcium concentration was measured before and after obtaining the measurements of force at the other 6 calcium concentrations. If there was >15% decline in force between the first and last force measurement at the maximal calcium concentration, we considered this as evidence of cell fragment degradation and this data was excluded from the analysis. Using these measurements, a force-pCa curve was plotted (Figure 2b) and the Hill equation was fit to derive the following contractile parameters: Fmax (the maximal calcium saturated developed force normalized to the
cross-sectional area of the myocyte), pCa50 (the calcium concentration at which the force is half maximal, a measure of calcium sensitivity), and Hill coefficient (the slope of the calcium-force relation, an index of myofilament cooperative activation). In order to minimize measurement variations for any single isolated myocyte, the individual patient contractile data reflect the average of measurement recordings for 3 to 5 myocytes per patient.

Sarcomeric Protein Phosphorylation Assessment

The remaining myocyte preparations not used for mechanical study were acetone precipitated to clamp their phosphorylation state and homogenized in 8M urea, 2.5M thiourea, 4% CHAPS, 10 mM EDTA, and a mixture of protease and phosphatase inhibitors as previously described. Protein concentration of these samples was measured using a BCA Protein Assay Kit (Thermo Scientific).

Phosphorylation levels of the cardiac sarcomeric proteins were determined by separating the proteins with 12% 1D-SDS-PAGE and fixing and staining with a phosphoprotein stain (ProQ Diamond Phosphoprotein Gel Stain, Invitrogen). After imaging, the same gels were rinsed and stained with a total protein stain (BioSafe Coomassie Blue, BioRad). All gels were imaged using a Typhoon 9410 Gel Imager (GE Lifesciences) and protein optical densities were measured using ImageJ (version 1.42 NIH). In order to adjust for subtle differences in protein loading, the phosphorylation levels were calculated by dividing the optical density of the each sarcomeric protein on the ProQ diamond gel by the optical density of the same protein on the Coomassie gel.
In the case of MyBPC, the total protein stain optical density merges with the abundant protein myosin, so the phosphorylation level of MyBPC on the phosphoprotein stain was normalized to essential myosin light chain (MLC-1) as prior studies have reported.\textsuperscript{20}

**Additional Assessment of Sarcomeric Proteins**

Site-specific phosphorylation of troponin I was assessed by Western blots. Proteins were separated with 12\% 1D-SDS-PAGE as above and transferred to PVDF membranes. After the membranes were blocked in 5\% BSA and rinsed with TBST, they were incubated overnight at 4 °C with a phosphospecific primary antibody to TnI phosphorylated at the putative protein kinase A (PKA) site, Serine 22,23 (Cell Signaling 1:1000) or to troponin I phosphorylated at the putative protein kinase C (PKC) site Serine 43 using an epitope specific phosphoserine antibody (Abcam 1:1000) as previously described.\textsuperscript{20} The blots were then washed and incubated with secondary antibody (anti-mouse from Sigma, 1:10000) for one hour at room temperature, washed, and visualized using enhanced chemiluminescence. Membranes were stripped and subsequently incubated in primary total cardiac TnI antibody (Fitzgerald, Inc 1:2500). Site specific phosphorylation was calculated by dividing the optical density of the phosphospecific antibody blot by the density of the total protein blot.

Changes in myosin heavy chain isoforms were assessed as previously described\textsuperscript{20} by separating proteins using modified 6\% 1D-SDS-PAGE and subsequent staining with BioSafe Coomassie Blue total protein stain. MLC-1 and MLC-2 phosphorylation and isoforms changes were assessed using 2D-SDS-PAGE\textsuperscript{21} and percent phosphorylated MLC-2 and percent atrial isoform of MLC-1 were calculated.
Changes in TnT isoform expression were assessed using modified Western blots as previously described. The primary cardiac TnT isoform antibody used was Ab-1 (Clone 13-11, Thermo scientific 1:1000).

Statistical Analysis

Results are expressed as mean ± standard deviation (SD). The paired t-test was used to compare differences between before and after LVAD implantation. The unpaired t-test was used to compare differences between before LVAD implantation failing and nonfailing and between after LVAD implantation failing and nonfailing groups. Statistical significance was defined as a two-tailed P-value of less than 0.05. The R version 2.9.1 (Vienna, Austria) statistical program was used for all analyses.

Results

Patient Characteristics

The baseline characteristics of patients with end-stage nonischemic cardiomyopathy requiring LVAD as a bridge to transplant are provided in Table 1. All patients were inotrope dependent with NYHA class IV HF at the time of LVAD implantation, and 7 of 8 patients required mechanical support with an intra-aortic balloon pump. The mean duration for the diagnosis of HF at the time of LVAD implantation was 59±22 months. Both first generation pulsatile displacement LVADs (HeartMate XVE, Thoratec, Pleasanton, CA) and second generation continuous axial flow LVADs (HeartMate II, Thoratec, Pleasanton, CA) were utilized. The mean duration of LVAD support was 143±41 days. LVAD support resulted in significant reductions in LV
echocardiographic dimensions, improvement in EF, and normalization of several hemodynamic measures as summarized in Table 2.

The 8 nonfailing patients (3 male and 5 female) were organ donors whose hearts were not utilized for transplant for non-cardiac reasons. The mean age of this group was 48 ± 8 years, the mean EF 70.6 ± 5.4%, and none of these patients had any prior cardiac history. Seven (87.5%) of these patients were on adrenergic vasopressor agents during the period of brain death and as organs were being harvested.

**Myocyte Size and Contractility Parameters**

Significant differences were noted for all myocyte fragment dimensions as summarized in Table 3. Myocytes obtained from patients before LVAD implant were significantly larger than myocytes from patients after LVAD implantation. However, the myocytes from patients after LVAD implantation were still larger than the myocytes obtained from nonfailing patients. Fmax doubled with LVAD support (3.6 ± 0.9 vs. 7.3 ± 1.8 mN/mm², p<0.001), but was still less than half of nonfailing subjects (7.3 ± 1.8 vs. 17.6 ± 1.8 mN/mm², p<0.001) as described in Table 4. The pCa50 was unchanged in all groups and the Hill coefficient was reduced in both LVAD groups relative to controls.

**Sarcomeric Proteins and Phosphorylation Levels**

Total TnI phosphorylation increased with LVAD support (12.8 ± 4.1 vs. 21.6 ± 9.4 OD units, p=0.030) (Table 5 and Figure 3). While there were no significant differences noted in the Serine 22,23 site specific phosphorylation of TnI, Serine 43 site specific phosphorylation of TnI decreased after LVAD (7.5 ± 2.2 vs. 5.2 ± 1.9 OD units,
p=0.044) (Figure 4). Total phosphorylation levels of MyBPC were higher in both failing groups compared with nonfailing donors (Table 5). Phosphorylation levels of TnT, Tm, and MLC-2 were not significantly different before and after LVAD (Table 5, and Figure 3).

There were no changes noted on 2D-SDS-PAGE in the percent phosphorylation of MLC-2 before and after LVAD (43±3 vs. 41±2%, p=0.341) and in the percent atrial isoform of MLC-1 before and after LVAD (23±5 vs. 21±7%, p=0.711). Furthermore, no differences were noted in myosin heavy chain isoforms before and after LVAD with only the β-isofrom being expressed in both groups of patients (Figure 5). Finally there was no evidence of altered TnT isoform expression in the before LVAD, after LVAD, and nonfailing groups. Total TnT content was unchanged between these groups.

Discussion

The main finding of this study is that in isolated skinned myocytes, there is a marked reduction in maximum developed force in patients with end-stage nonischemic cardiomyopathy compared to nonfailing donors. This marked reduction in force is only partially improved with LVAD support. Furthermore, there is strong evidence that structural changes accompany these changes in force at the organ level (reduction in LV size) as well as at the cellular level (reduction of all myocyte dimensions) and these correlate with functional changes at both the organ level (improvement in EF) and cellular level (improvement in maximum force). Despite these significant changes in structural and mechanical parameters, unloading of the LV with LVAD support did not
change the biochemical properties of the sarcomere other than a change in TnI phosphorylation.

Our findings confirm that contractile dysfunction in human heart failure at least in part resides at the level of the cardiac myofilament. This is independent of cell loss or changes in the cardiac interstitium and certainly argues that therapies to treat heart failure need to acknowledge sarcomeric function. To place these changes in context, a prior report using a similar experimental protocol in human samples reported ~30% reductions in myocyte Fmax in diabetics with preserved EF compared to control patients (14.6±1.7 vs. 20.6±3.7 mN/mm², p<0.05). The Fmax of the failing groups before and after LVAD from the current study are more dramatic (~60%) than seen in this prior report, consistent with the severe reductions in contractile function at the organ level as assessed by EF.

There are a number of cellular and molecular changes in the heart that occur with LVAD support and these encompass the most basic aspects of genetic regulation and involve a complex, interconnected cascade of changes. While there have been two prior studies that have assessed for changes in myocyte contractility with LVAD, this is the first study to directly measure isometric force of skinned myocytes from paired samples before and after LVAD support. The two prior studies (one of which used paired pre/post LVAD samples) involved patients with both ischemic and nonischemic/idiopathic cardiomyopathies. Using in vitro motility and unloaded cell shortening assays, the authors reported improvements in contractility in myocytes obtained from patients with HF vs. patients with HF supported by LVAD. Our assessment of myocyte contractility also differs from the two prior reports in that we limited our analysis to only those patients with nonischemic cardiomyopathy (a global
pathologic process that involves the entire LV) as opposed to ischemic cardiomyopathy (a regional pathologic process based on areas of infarct/ischemia from coronary artery disease). The prior reports included data from patients with ischemic cardiomyopathy, and the before LVAD tissue (from the LV apex) would be inherently different than the after LVAD tissue depending on the regions of LV infarction making comparisons difficult. The results of our study confirm that among patients with nonischemic cardiomyopathy, improvement in contractility at the sarcomeric level is possible with LVAD support; however normalization of forces to levels seen in nonfailing subjects does not occur using standard LVAD protocols. This is concordant with organ level assessment of contractility where EF improved from 10.0 to 25.6% with LVAD support; which is still half that seen in a nonfailing control hearts. This may in part explain clinically why the majority of LVADs cannot be successfully explanted.

The cellular mechanisms by which contractility is depressed in these HF samples and why there is only partial reversal with mechanical unloading is not unequivocally answered in this study, although there is suggestive evidence that points towards both structural and biochemical mechanisms. The fact that the Hill coefficient, a marker of protein cooperativity, was reduced in both HF groups, coupled with the changes in MyBPC phosphorylation suggest that functional interactions between actin and myosin might have been compromised in both HF groups. This hypothesis is supported by the cell morphology data which suggest that sarcomere cross-bridge (and perhaps lattice) spacing is tightly coupled with contractile performance both in the two HF groups and also in the donor heart specimens, a finding which reflects previous studies.
demonstrating that contractile parameters in isolated muscle were influenced in a stepwise fashion by osmotic determinants that influenced lattice architecture.\textsuperscript{25,26}

The mechanism for the partial recovery of contractile function following LVAD support might be in part reflective of contractile protein phosphorylation changes. Total TnI phosphorylation was lower before LVAD support compared to after LVAD and nonfailing samples which may be due to down-regulation of β-adrenergic receptors in inotrope dependent patients with end-stage HF. The increase in TnI phosphorylation after LVAD might be reflective of normalization of β-adrenergic receptor function. Despite this, there was an increase in TnI phosphorylation at serine 43—a putative PKC site—in the pre LVAD samples which decreased following LVAD support. This finding is consistent with a substantial literature that suggests that heart failure, both in humans and in experimental animals, is associated with an increase in PKC activation,\textsuperscript{27,28} and that PKC dependent phosphorylation of TnI is associated with depressed myofilament force development.\textsuperscript{29-31} The finding also provides a plausible explanation as to why phosphatase treatment of myofilament preparations from HF patients improves contractile performance despite overall low levels of overall contractile protein phosphorylation.\textsuperscript{9} The fact that there was no change seen in TnI phosphorylation at the putative PKA site, serine 22,23 despite postulated changes in adrenergic receptor activity before and after LVAD, may reflect the somewhat promiscuous nature of this site which can be targeted both by PKA and PKC,\textsuperscript{29} the former likely increasing after LVAD and the later declining.

Not seen in this study were changes in phosphorylation of other contractile proteins or isoform shifts before and after LVAD support. In particular, and in contrast
to studies in experimental animals, we did not see a shift at the protein level in the α/β myosin heavy chain isoform ratio or in troponin T isoform distribution. This is particularly important to note as mechanical unloading of the normal LV in experimental animals does result in atrophy associated with a recapitulation of the fetal gene program whereas in this study, unloading was associated with a normalization of ventricular size without isoform changes.

**Limitations**

We acknowledge a number of limitations to this study. The overall number of patients in the analysis is small and all were from a single center’s LVAD program. There were no differences in the results between patients supported with pulsatile-flow HeartMate XVE pumps versus continuous-flow HeartMate II pumps, although our small numbers preclude accurate subgroup analysis to definitively test for differences in the type of mechanical unloading. In addition, the echocardiographic measures of LV size and EF during LVAD support were obtained from retrospective review and were thus obtained on the LVAD settings that were clinically indicated for the patient. While these assessments do partially reflect the influence of the LVAD, some component of native LV function also contributes as on pump measures of LV size and EF are often used in the initial screening assessments to determine whether patients should have further testing to assess for recovery. Myocyte dimensions were measured from the isolated skinned myocyte fragments that were used for mechanical force measurements rather than a specific histological stain of intact tissue. Despite this different methodology, the cross-sectional areas obtained in this study were very similar to those reported recently.
using such traditional histological techniques\textsuperscript{6} and the overall trends are well in line with other published reports.\textsuperscript{5}

The nonfailing tissue was obtained from organ donors, and the majority of these patients were receiving adrenergic agents prior to and during harvest, so adrenergic mediated pathways were likely activated in these patients. Furthermore, concomitant medical therapy during LVAD support, such as β-blockade, varied and may have influenced some of the sarcomeric mechanical properties as has been previously demonstrated.\textsuperscript{35} In addition, while we believe the comparison between LVAD (before and after) and nonfailing donor hearts are illuminating, it is worth noting that the tissue procurement strategies were by necessity somewhat different in that the nonfailing and after LVAD hearts were excised en bloc whereas the before LVAD specimens were taken from small tissue cores obtained from beating hearts. Finally, the before and after LVAD samples were obtained in the operating room after the patient was induced with general anesthesia and placed on cardiopulmonary bypass. These procedures may have affected the sarcomeric protein phosphorylation background. Despite these limitations, the current study remains the most comprehensive examination of the effects of LVAD support on the sarcomere and thus merits attention.

**Conclusion**

There is significant improvement in LV and myocyte size with LVAD support, but there is only partial recovery of EF and myocyte contractility. The architectural changes of LVAD support were associated with a limited spectrum of biochemical changes which suggest that both lattice spacing and PKC activation might contribute to
contractile dysfunction. These data further suggest that additional interventions beyond mechanical unloading may be needed to alter biochemical remodeling of the sarcomere to further enhance myofilament and organ level recovery.

The Fmax is the maximum calcium-saturated developed force normalized to the cross-sectional area of the myocytes, pCa50 is the calcium concentration at which the force is half maximal and represents a measure of myofilament calcium sensitivity, Hill coefficient is the slope of the calcium-force relation and is an index of myofilament cooperative activation.

Figure Legends

Figure 1. Photomicrograph example of an isolated skinned myocyte fragment attached to the force transducer and motor in relaxing solution for mechanical contractile experiments. The visible sarcomere striations were set at 2.1 μm for all myocyte experiments.

Figure 2.

(a) Representative tracing of force measurements from the experimental protocol. After the myocyte had achieved a steady force in the calcium containing activation solution, it was rapidly step shortened to break cross-bridges (top tracing) and the maximum force for the particular activation solution was then recorded (bottom tracing).

(b) Representative plot of the force-calcium relation. Force is shown plotted against the inverse log of the calcium concentration (pCa). The Fmax (the maximal calcium saturated developed force normalized to the cross-sectional area of the myocyte), pCa50 (the calcium concentration at which the force is half maximal, a measure of calcium sensitivity), and Hill coefficient (the slope of the calcium-force relation, an index of myofilament cooperative activation) for each myocyte were derived from these force-pCa curves.

Figure 3. 12% 1D-SDS-PAGE images stained with a total phosphoprotein stain (ProQ Diamond Phosphoprotein Gel Stain) in panel A and a total protein stain (BioSafe...
Coomassie Blue) in panel B demonstrate the increase in total TnI phosphorylation with LVAD support and higher MyBPC phosphorylation in both failing samples compared with nonfailing donors. Sarcomeric protein phosphorylation levels were calculated by dividing the optical density of the each sarcomeric protein on the ProQ diamond gel by the optical density of the same protein on the Coomassie gel. MyBPC was normalized to MLC-1 as noted in the text.

NF=nonfailing, MyBPC=myosin binding protein C, TnT=troponin T, Tm=tropomyosin, TnI=troponin I, MLC-1=myosin light chain 1, MLC-2=myosin light chain 2

**Figure 4.** Western blots of phosphorylated troponin I (TnI) demonstrate while there were no significant differences in Serine 22,23 site specific phosphorylation of TnI, Serine 43 site specific phosphorylation of TnI decreased after LVAD. Samples were separated on 12.5% SDS-PAGE and probed with antibodies against phosphoserine 22/23, phosphoserine 43, and cardiac TnI (for total protein). NF=nonfailing.

**Figure 5.** 6% 1D-SDS-PAGE separation of α and β myosin before and after LVAD demonstrates that only the β-isoform is expressed in both groups. The last lane is a mixture of 50% nonfailing human with 50% nonfailing mouse and illustrates adequate separation of α and β myosin isoforms.
Incomplete Recovery of Myocyte Contractile Function Despite Improvement of Myocardial Architecture With Left Ventricular Assist Device Support
